The following articles are US Government works in the public domain and are not subject to copyright:

Adipocyte Fat Mobilization: The Regulatory Roles of Perilipin 1, Adipose Triglyceride Lipase, and Hormone-Sensitive Lipase
Arf Family
Calcium Signaling: Calmodulin-Dependent Phosphatase
Cyclic AMP Receptors of *Dictyostelium*
Cyclic Nucleotide Phosphodiesterases
Cytokines
DNA Mismatch Repair in Disease and Aging
DNA Polymerase β , Eukaryotic
Endocytosis
Eukaryotic Chemotaxis
Gs Family of Heterotrimeric G Proteins
Inositol Phosphate Kinases and Phosphatases
Phospholipase C
Prions of Yeast and Fungi: Proteins Acting as Genes
Riboswitches
Structure and Regulation of Pyruvate Dehydrogenases

EDITORS-IN-CHIEF

M. Daniel Lane, Ph.D. is Distinguished Service Professor of Biological Chemistry at the Johns Hopkins Medical School. He received B.S. and M.S. degrees from Iowa State University, a Ph.D. degree from the University of Illinois and an honorary Doctor of Humane Letters degree, from Iowa State University. He did a Senior Postdoctoral Fellowship with Professor Feodor Lynen at the Max-Planck Institute Für Zellchemie in Munich. Following faculty positions at Virginia Tech and New York University School of Medicine, he joined (in 1970) the faculty at the Johns Hopkins Medical School where he served as DeLamar Professor and Director of the Department of Biological Chemistry from 1978 to 1997. He was elected to membership in the National Academy of Sciences and the American Academy of Arts and Sciences (1987) and as a Fellow of the American Society of Nutritional Sciences (1996). He received the Mead Johnson Award from the American Society for Nutritional Sciences and the William C. Rose Award from the American Society for Biochemistry and Molecular Biology and served as President of the American Society of Biochemistry and Molecular Biology. He served on numerous editorial boards including the Journal of Biological Chemistry and the Annual Reviews of Biochemistry. With William Lennarz he co-edited the first edition (2004) of the Encyclopedia of Biological Chemistry. Currently he is Associate Editor for Biochemical and Biophysical Research Communications. His early work focused on enzymatic CO₂ fixation reactions, notably the mechanisms by which the B-vitamin, biotin, functions in carboxylases. His research on acetyl-CoA carboxylase, key regulatory enzyme of fatty acid synthesis, led him to his present interests in the basic mechanisms of lipogenesis, adipogenesis and the hypothalamic control of energy balance.

William J. Lennarz received his B.S. in Chemistry from Pennsylvania State University and a Ph.D. in Organic Chemistry from the University of Illinois. Subsequently he carried out postdoctoral work at Harvard with Konrad Bloch on fatty acid biosynthesis. In 1962 he was appointed Assistant Professor at Johns Hopkins in the Department of Physiological Chemistry. After promotion to Associate Professor in 1967, and full Professor in 1971, he remained at Hopkins until 1983. At that time, he was appointed Robert A. Welch Professor and Chair of the Department of Biochemistry and Molecular Biology at the University of Texas Cancer Center, M.D. Anderson Hospital. In 1989 he became a Leading Professor and Chair of the Department of Biochemistry and Cell Biology at SUNY at Stony Brook. In 1990 he founded and became Director of the Institute for Cell and Developmental Biology at Stony Brook.

Dr. Lennarz has served on many national and international committees. He has served as President of the Biochemistry Chairman's Organization, President of the American Society for Biochemistry and Molecular Biology, and President of the Society for Glycobiology. He was a member of the Executive Committee of the International Union of Biochemistry and Molecular Biology for almost a decade.

He has presented special lectures at the University of Notre Dame, the NIH, the University of West Virginia, Johns Hopkins University, Florida State University, the University of California at San Diego, the University of Arkansas, Indiana University, and the Medical College of Virginia.

He is a member of the National Academy of Sciences. The focus of his early work was on lipids and bacterial cell surfaces. More recent efforts have been in the structure, biosynthesis, and function of cell surface glycoproteins. The biosynthesis studies were initially carried out in liver and oviduct, but these efforts now are focused in yeast. The functional studies have concentrated on the role of cell surface glycoproteins in fertilization and early development in the sea urchin and, more recently, the frog. He served as Distinguished Professor and Chair of his department. He now is Distinguished Professor Emeritus.

EDITORIAL BOARD

Wolfgang Baumeister was born on November 22, 1946 in Wesseling near Cologne. Study of biology Münster and Bonn University, doctorate Düsseldorf University (1973), Habilitation in biophysics Düsseldorf University (1978), Heisenberg Scholarship Cambridge/England, head of a group (C3 level) at the Max Planck Institute for Biochemistry (1981), Adjunct Professor Düsseldorf University (1982), Adjunct Professor Chemistry Dept. TU Munich (1987), Director and Scientific Member at the Max Planck Institute of Biochemistry (since 1988), Honorary Professor, Physics Dept., TU Munich (2000). He was made a fellow with the German Academy of Sciences Leopoldina in 2001 and was elected as a Foreign Associate with the US National Academy of Sciences in 2010.

Wolfgang Baumeister has been honored with numerous awards for his research including the Otto Warburg Medal of the German Society for Biochemistry and Molecular Biology (1998), the prize of the Geneva-based Louis-Jeantet Foundation for Medicine (2003), the Ernst Schering Prize (2006), the Schleiden Medal of the German Academy of Sciences Leopoldina (2005), and the Harvey Prize in Science and Technology of the Technion, Haifa (2005).

Ernesto Carafoli was born in 1932, in Italy. He gained his M.D. in 1957 at the University of Modena, Italy; "Abilitation" (Libera Docenza) in General Pathology (1965) and in Biochemistry (1968); Fogarty International Post-doctoral Fellow in the Dept. of Physiological Chemistry of the Johns Hopkins University, Baltimore, MD, USA (1963–1965); Visiting Lecturer in the same department 1968–1969; Assistant Professor, then Associate Professor of General Pathology in the University of Modena School of Medicine, (1959 to 1972); Professor of General Pathology, University of Padova School of Medicine (Italy) (1973); Professor of Biochemistry, Swiss Federal Institute of Technology (ETH) (Zurich, Switzerland), (1973 to 1998); Chairman of the Dept. of Biochemistry of the Swiss Federal Institute of Technology (ETH) in 1978 and 1987 to 1991; Professor of Biochemistry, University of Padova, School of Medicine, Italy (since 1990). From 1971 to 1991 Visiting Professor for various periods in several Italian Universities, at the University of Nairobi (Kenya), at the Universidad Nacional Autonoma of Mexico, Mexico City (Mexico), at the Universidad Central de Venezuela, Caracas (Venezuela), and at Case Western Reserve University, Cleveland (OH, USA). He has been Fogarty Scholar in Residence at the NIH from 1985 to 1988. Co-founder of the Venetian Institute of Molecular Medicine (Padova, Italy), of which he was the first Scientific Director (2000 to 2005). He has received numerous awards and honors including five Doctor Honoris Causa degrees. He is Member of several Academies, including the Johns Hopkins Society of Scholars, and he has been made "Grande Ufficiale" of the Order of Merit of the Republic of Italy, 2006.

Dr. Carafoli has been a member of a number of professional Societies, including the Swiss Biochemical Society, the Biochemical Society, the American Society for Cell Biology, the American Society of Biological Chemistry and Molecular Biology (Honorary Member), the Society of General Physiology, the Biophysical Society, the Italian Society of Biochemistry. He has been a member of the Editorial Board of numerous journals in the area of Biochemistry, Biophysics, and Cell Biology. He has been co-organizer of about 50 International Congresses and Symposia, and of about 25 Advanced Courses, (held in a dozen countries on behalf of FEBS, ICRO/UNESCO, the Gulbenkian Foundation, and WHO). He has delivered lectures (including a number of Plenary and Keynote lectures) at about 350 International Congresses, Symposia, Colloquia. He has written over 500 articles in refereed journals on topics of muscle biochemistry, membrane biochemistry, mitochondrial bioenergetics, membrane transport of ions (calcium specially by pumps) regulation of calcium metabolism, and over 100 book chapters and 70 invited review articles. He has edited about 20 books on topics related to his work.

Pierre A. Coulombe is the E.V. McCollum Professor and Chair of the Department of Biochemistry and Molecular Biology at the Bloomberg School of Public Health at Johns Hopkins University in Baltimore, Maryland. He holds several joint appointments in the School of Medicine and the same institution. Dr. Coulombe obtained a Ph.D. degree from Université de Montréal in Canada and underwent postdoctoral training at the University of Chicago. At that time, he and Dr. Elaine Fuchs discovered that mutations in keratins elicit epithelial fragility in transgenic mice and in individuals suffering from inherited blistering diseases. He continues to explore the properties and function of keratin genes and proteins in the setting of tissue repair and cancer.

Nancy L. Craig is an Investigator with the Howard Hughes Medical Institute, as well as a Professor of Molecular Biology and Genetics at the Johns Hopkins University School of Medicine, where her work is focused on the molecular mechanisms by which transposable elements move and how they can be exploited for genome engineering. After receiving a bachelor's degree in biology and chemistry from Bryn Mawr College, she did graduate work on cellular responses to DNA damage in *E. coli* with Jeffrey Roberts at Cornell University, leading to her Ph.D. degree in biochemistry. As a postdoctoral fellow at the National Institutes of Health, she studied the mechanism of site-specific recombination of bacteriophage lambda with Howard Nash. Before joining HHMI, she was Associate Professor of Microbiology and Immunology and of Biochemistry and Biophysics at the University of California, San Francisco, where she began her research on Tn7 transposition. Dr. Craig is a Member of the National Academy of Sciences and the American Academy of Arts and Sciences. She is also a Fellow of the American Association for the Advancement of Science and the American Academy of Microbiology.

Joel Moss, M.D., Ph.D. is Deputy Chief of the Cardiovascular and Pulmonary Branch, National Heart, Lung, and Blood Institute at the National Institutes of Health, Bethesda, Maryland, USA. He graduated from Brandeis University in 1967, Summa Cum Laude with Honors in Chemistry. In 1972, he received M.D. and Ph.D. degrees from New York University School of Medicine, with his dissertation in the Department of Biochemistry under the mentorship of Dr. M. Daniel Lane. Following an internship and residency in medicine at the John Hopkins Hospital, he completed a post-doctoral fellowship with Dr. Martha Vaughan and pulmonary fellowship with Dr. Ronald Crystal in the National Heart, Lung, and Blood Institute (NHLBI) at the National Institutes of Health. Dr. Moss has coauthored over 600 scientific papers on basic and clinical research, edited or co-authored several books, and is a co-inventor of biotechnology patents. Dr. Moss was a member of the NHLBI Institutional Review Board 1988 to 2006, and its Chair 1995 to 2006. In this regard, he has coauthored a textbook with Dr. Evan DeRenzo entitled: "Writing Clinical Research Protocols: Ethical Considerations". Dr. Moss has received multiple awards, including the Passano Foundation Young Investigator Award (1981), the AFCR Young Investigator Award (1981), and the LAM Foundation Award (1999, 2010). He is a Fellow of the American College of Chest Physicians. Dr. Moss is a member of Phi Beta Kappa, Alpha Omega Alpha, the American Society for Biochemistry and Molecular Biology, Association of American Physicians, American Thoracic Society, and the American Society for Clinical Investigation (ASCI), of which he has served as a Councilor and Vice President.

In his clinical research, Dr. Moss has focused on destructive lung diseases (e.g., lymphangioleiomyomatosis, cystic fibrosis), with primary emphasis on the roles of infection/inflammation and susceptibility/modifier genes on disease progression and severity. His LAM research centers on the abnormal smooth muscle-like cells (LAM cells) that proliferate in the lungs, lymphatics, and kidneys, and are responsible for cystic lung destruction and abnormalities in the lymphatic system. Subjects of his basic research include guanine nucleotide-binding regulatory proteins and post-translational modification of proteins by ADP-ribosylation.

Carole Parent obtained her B.Pharm. and M.Sc. degrees from the University of Montréal in Canada and her Ph.D. in Pharmacy from the University of Illinois at Chicago. She then pursued postdoctoral studies in the laboratory of Dr. Peter Devreotes at Johns Hopkins. In 2000, she joined the Laboratory of Cellular and Molecular Biology at the Center for Cancer Research (NCI, NIH) where she is now Senior Investigator and Deputy Chief. Using three complementary model systems, her research interests are centered on understanding how cells detect and respond to external chemotactic signals and, in particular, how the relay of chemotactic signals from cell-to-cell impacts single and group cell migration.

HOW TO USE THE ENCYCLOPEDIA

The *Encyclopedia of Biological Chemistry* is a comprehensive and authoritative study covering the field of biochemistry. It includes over 500 articles on various aspects of this subject, contained in four volumes. Each article provides a focused description of the given topic, intended to inform a broad range of readers, ranging from students, to research professionals, and interested others. Each article serves as a comprehensive overview of a given area, providing both breadth of coverage for students, and depth of coverage for research professionals.

All articles in the encyclopedia are arranged alphabetically by subject in the table of contents. The index is located in volume 4. Article titles generally begin with the key word or phrase indicating the topic.

Each article contains a glossary, cross-references to other related encyclopedia articles, and further readings and relevant websites for additional information. The glossary contains terms that may be unfamiliar to the reader, with each term defined in the context of its use in that article. Thus, a term may

appear in the glossary for another article defined in a slightly different manner or with a subtle nuance specific to that article. For clarity, we have allowed these differences in definition to remain so that each article is fully understandable on its own.

Each article has been cross-referenced to other related articles in the encyclopedia at the close of each article. We encourage readers to use the cross-references to locate other encyclopedia articles that will provide more detailed information about a subject.

The further readings include recent secondary sources to aid the reader in locating more detailed or technical information. Review articles and research articles that are considered of primary importance to the understanding of a given subject area are also listed. These suggested readings are not intended to provide a full reference listing of all material covered in the context of a given article, but are provided as next steps for a reader looking for additional information.

PREFACE

Biological Chemistry encompasses the “*chemistry of life*”, more specifically the chemistry of the compounds and processes that constitute living organisms. The ultimate goal is to understand and define biology at a mechanistic level. This was aptly stated in an historical treatise on the founding of the *Journal of Biological Chemistry*, where John Edsall quoted a statement in a letter from J. L. Loeb (in Berkeley), “The future of biology lies with those who attack its problems from a chemical point of view.” What was an emerging field in 1900 with its origins in physiology, nutrition, and chemistry has now broadened to include numerous other fields including mechanistic enzymology, molecular biology, structural biology, cell biology, genomics, proteomics, metabolomics, bioinformatics, and others, that were not defined as discrete fields in that era.

Modern biochemistry (biological chemistry) really began with the accidental discovery, by Eduard Buchner in 1897, that a cell-free yeast extract could carry out fermentation of glucose to alcohol and CO₂ *in the absence of intact cells*. He named the dissolved substance responsible for this process zymase, the substance(s) we now refer to as enzymes. Importantly, Buchner recognized the significance of his discovery. This ended the dogma of the time, perpetuated by Louis Pasteur, the concept of *vitalism* that fermentation (and presumably other complex biological phenomena) required the action of intact cells. Thus, serendipity and a prepared mind ushered in a new period of discovery. It became possible to dissect complex physiological processes and to study them with preparations free of the constraints of intact cells. Once a metabolic pathway/process was established, it became possible to purify the enzymes, cofactors, and substrates involved, to reconstitute the process with purified components and to characterize the components chemically. What followed was an information explosion in the field of biochemistry and progression through a series of trends, each “in vogue” in its time. The identification of the dietary essentials, the hunt for the vitamins/cofactors, the hormones, identification of metabolic pathways and the enzymes involved, oxidative phosphorylation, protein synthesis, molecular biology — each developed as a primary focus.

The need to associate chemistry with function came early and was evident in the naming of Departments and Journals. Over time names changed from Agricultural Chemistry to Physiological Chemistry to Biochemistry to Biological Chemistry. An example is the Department of Biochemistry at the University of Wisconsin, which began in 1883 as the Department of Agricultural Chemistry.

Where are we headed? We have reached the point where the borders of these areas have become blurred. What constitutes cell biology, molecular biology, genetics, developmental biology, physiology, immunology — ultimately reduces to chemistry. To understand these processes we must know what the molecules are and understand how they interact, i.e. the basic chemistry. That is what the *Encyclopedia of Biological Chemistry* is about.

The breadth of content of this encyclopedia aims to cover major topics of modern biochemistry, each authored by an expert in the area. We feel that the coverage is broad and we have been inclusive in choice of topics. The encyclopedia is a reference work containing over 500 articles with nearly 900 authors and coauthors. Each article/topic covers an important area of the field that reflects the point of view of the authors. Together the articles cover virtually every aspect of biology for which we have “mechanistic” information. For those who wish to probe more deeply into a topic, references to review articles are included at the end of each article. The editorial board that made decisions on coverage consists of eight members, each an expert representing a major area in the field of biochemistry. An effort was to make coverage as complete as possible. The content is pitched at a level we hope interpretable to interested individuals with some background in chemistry and biology. It is intended for such individuals rather than specialists with extensive scientific backgrounds in specific areas. It is aimed at the generalist as opposed to the specialist.

VOLUME 1

AAA-ATPases <i>J Martin and A N Lupas</i>	1
ABC Transporters <i>A Goffeau and B De Hertogh</i>	7
Actin Assembly/Disassembly <i>H N Higgs</i>	12
Actin-Capping and -Severing Proteins <i>S Maiti and J R Bamburg</i>	18
Actin Organization <i>T Svitkina</i>	27
Actin-Related Proteins <i>R D Mullins</i>	36
Adenylyl Cyclases <i>R Taussig</i>	42
Adipocyte Fat Mobilization: The Regulatory Roles of Perilipin 1, Adipose Triglyceride Lipase, and Hormone-Sensitive Lipase <i>K T Dalen, C Londos, and A R Kimmel</i>	47
Adipogenesis <i>M D Lane</i>	52
Adrenergic Receptors <i>D B Bylund</i>	57
Affinity Tags for Protein Purification <i>J J Falke and J A Corbin</i>	61
Algal Hydrogen Production <i>U M N Murthy and M L Ghirardi</i>	66

Allosteric Regulation <i>B S Cooperman</i>	71
Alternative Splicing <i>K Lynch and L Motta-Mena</i>	75
Alternative Splicing: Regulation of <i>Drosophila melanogaster</i> Sex Determination <i>J K M Penn, P Graham, P Schedl, and H K Salz</i>	81
Amine Oxidases <i>G Floris and A Finazzi Agrò</i>	87
Amino Acid Metabolism <i>L Cynober</i>	91
Aminopeptidases <i>R A Bradshaw</i>	97
Amyloid <i>R Wetzel</i>	100
Anaplerosis <i>R R Russell III and H Taegtmeyer</i>	105
Angiotensin Receptors <i>T Inagami</i>	111
Anorexigenic and Orexigenic Gut Peptides <i>P S Petersen and T H Moran</i>	115
Aquaporin Water Channels <i>K Liu and P Agre</i>	120
Arachidonic Acid Regulated Calcium Channel <i>T J Shuttleworth</i>	127
Arf Family <i>G Pacheco-Rodriguez, J Moss, and M Vaughan</i>	134
Aspartic Proteases <i>B M Dunn</i>	137
ATP in Plant Mitochondria: Substrates, Inhibitors, and Uncouplers <i>K L Soole and R I Menz</i>	141
ATP Synthesis: Mitochondrial Cyanide-Resistant Terminal Oxidases <i>J N Siedow</i>	145
Autophagy in Fungi and Mammals <i>J Geng, D J Klionsky, and J-L Guan</i>	149
B ₁₂ -Containing Enzymes <i>V Bandarian and R G Matthews</i>	155
B-Cell Antigen Receptor <i>T M Yankee</i>	161
Bcl2 Family: Cell Death Enhancers and Inhibitors <i>D L Vaux</i>	165
Bile Salts <i>L Maillette de Buy Wenniger, T Pusch, and U Beuers</i>	167
Biochemistry: Niacin/NAD(P) <i>K L Bogan and C Brenner</i>	172

Biochemistry of Development: Striated Muscle <i>R Bassel-Duby and E N Olson</i>	179
Biochemistry of Hematopoiesis <i>A D Friedman</i>	187
Biochemistry of Liver Regeneration <i>B Ochoa and A M Diehl</i>	190
Biochemistry of Neurogenesis <i>K Christian, H Song, and G-L Ming</i>	196
Biochemistry of Thiamine and Thiamine Phosphate Compounds <i>L Bettendorff and P Wins</i>	202
Bioenergetics and the Mitochondrial Genome <i>D C Wallace</i>	210
Bioenergetics: General Definition of Principles <i>D G Nicholls</i>	217
Biotin <i>S W Polyak and A Chapman-Smith</i>	221
Biotinylation of Proteins <i>R A Kohanski</i>	226
Bmp Signaling and Vascular Disease <i>J Lowery and M de Caestecker</i>	229
Bradykinin Receptors <i>R M Burch</i>	240
Branched-Chain Amino Acids <i>D T Chuang</i>	244
Brassinosteroids <i>S D Clouse</i>	250
Cadherin-Mediated Cell–Cell Adhesion <i>M Lowndes and W J Nelson</i>	255
Cadherin Signaling <i>D B Sacks</i>	261
Calcitonin Gene-Related Peptide and Adrenomedullin Receptors <i>D L Hay, A C Conner, and D R Poyner</i>	265
Calcitonin Receptor <i>S I Girgis, N Moradi-Bidhendi, and L Mancini</i>	270
Calcium-Binding Proteins: Cytosolic (Annexins, Gelsolins, and C ₂ -Domain Proteins) <i>J Krebs</i>	275
Calcium, Biological Fitness of <i>R J P Williams</i>	281
Calcium-Buffering Proteins: Calbindin <i>L J Mady, F Haleem, and S Christakos</i>	284
Calcium-Buffering Proteins: ER Luminal Proteins <i>J Groenendyk and M Michalak</i>	290
Calcium/Calmodulin-Dependent Protein Kinase II <i>A Hudmon and H Schulman</i>	297

Calcium/Calmodulin-Dependent Protein Kinases <i>A J Robison and R J Colbran</i>	304
Calcium in the Regulation of Gene Expression <i>M Rivas and J R Naranjo</i>	310
Calcium-Modulated Proteins (EF-Hand) <i>R H Kretsinger</i>	316
Calcium Oscillations <i>M Brini</i>	322
Calcium-Sensing Receptor (CaSR) <i>J Tfelt-Hansen and E M Brown</i>	326
Calcium Signaling by Cyclic ADP-Ribose and NAADP <i>L Santella and J T Chun</i>	331
Calcium Signaling: Calmodulin-Dependent Phosphatase <i>C B Klee and S Li</i>	337
Calcium Signaling: NO Synthase <i>Z-Q Wang and D J Stuehr</i>	342
Calcium Transport in Mitochondria <i>R Rizzuto and M Brini</i>	347
Calpain <i>H Sorimachi, S Hata, and Y Ono</i>	353
Carbohydrate Chains: Enzymatic and Chemical Synthesis <i>T J Tolbert and C-H Wong</i>	362
Carbohydrate Metabolism in the Central Nervous System <i>I Simpson and S J Vannucci</i>	368
Carbohydrate-Responsive Element Binding Protein <i>K Uyeda and H Yamashita</i>	374
Cardiac Excitation–Contraction Coupling <i>D M Bers and S Despa</i>	379
Carnitine and β -Oxidation <i>J Kerner and C L Hoppel</i>	384
Caspases and Cell Death <i>D W Nicholson and G Melino</i>	388
Catalysis by RNA, Structural Themes: Group I Introns <i>B L Golden</i>	397
Cell Cycle: Control of Entry and Progression through S Phase <i>S L Forsburg</i>	401
Cell-Cycle Controls in G ₁ and G ₀ <i>A Narasimha, W Shi, and S F Dowdy</i>	406
Cell Cycle: DNA Damage Checkpoints <i>M D Weitzman and J Y J Wang</i>	410
Cell Cycle: Mitotic Checkpoint <i>T J Yen</i>	417
Cell Death by Apoptosis and Necrosis <i>V Ermer and P Nicotera</i>	423

Cell–Matrix Interactions <i>J A Askari and M J Humphries</i>	426
Cell Migration <i>J V Small</i>	430
Cell Migration within Three-Dimensional Matrices <i>P J Keely</i>	436
Centromeres <i>B A Sullivan</i>	446
c- <i>fes</i> Proto-Oncogene <i>T E Smithgall</i>	451
Chaperonins <i>A Bracher and F U Hartl</i>	456
Chemiluminescence and Bioluminescence <i>T O Baldwin</i>	461
Chemiosmotic Theory <i>P R Rich</i>	467
Chemistry of Alzheimer Disease <i>G H Sack Jr.</i>	473
Chemokine Receptors <i>T Sobolik-Delmaire, D Raman, J Sai, G-H Fan, and A Richmond</i>	480
Chemolithotrophy <i>A B Hooper and A A DiSpirito</i>	486
Chemotactic Peptide/Complement Receptors <i>E R Prossnitz and L A Sklar</i>	493
Chlorophylls and Carotenoids <i>H Scheer</i>	498
Chloroplasts <i>N Rascio</i>	506
Chloroplast Signaling and Redox Control <i>J-D Rochaix</i>	511
Cholesterol Synthesis and Regulation <i>P J Espenshade</i>	516
Chromatin: Methyl-CpG-Binding Proteins <i>D G Skalnik</i>	521
Chromatin: Nucleosome Positioning – the GAL Promoter <i>D Lohr</i>	525
Chromatin: Physical Organization <i>C L Woodcock</i>	530
Chromosome Organization and Structure, Overview <i>E Gracheva and S C R Elgin</i>	535
Coenzyme A <i>M D Lane</i>	539
Collagenases <i>K Holmbeck and H Birkedal-Hansen</i>	542

Collagens <i>D J Prockop</i>	545
Color Vision <i>G H Jacobs</i>	550
Conservative Site-Specific Recombination <i>M C M Smith</i>	555
Cyclic AMP Receptors of <i>Dictyostelium</i> <i>D Hereld, Y Kamimura, and P N Devreotes</i>	562
Cyclic GMP Phosphodiesterases <i>S H Francis and J D Corbin</i>	567
Cyclic Nucleotide-Dependent Protein Kinases <i>S H Francis and J D Corbin</i>	574
Cyclic Nucleotide Phosphodiesterases <i>V C Manganiello and E Degerman</i>	580
Cyclic Nucleotide-Regulated Cation Channels <i>M Biel</i>	586
Cysteine Proteases <i>D J Buttle and J S Mort</i>	589
Cytochrome <i>bc</i> ₁ Complex (Respiratory Chain Complex III) <i>B L Trumpower</i>	593
Cytochrome <i>c</i> <i>H Tuppy and G Kreil</i>	599
Cytochrome Oxidases, Bacterial <i>P Brzezinski and P Ädelroth</i>	602
Cytochrome P-450 <i>R Bernhardt</i>	607
Cytokines <i>S J Levine</i>	613
Cytokinesis <i>V Srivastava and D N Robinson</i>	622
Cytokinin <i>T Schmölling</i>	627
Cytoskeletal Motors: General Principles <i>R S Rock</i>	632
Desmosomes and Hemidesmosomes <i>V Todorović, K R Kligys, R L Dusek, J C R Jones, and K J Green</i>	636
Detergent Properties <i>D R McCaslin</i>	644
Diabetes <i>S M Blackman and D W Cooke</i>	649
Diacylglycerol Kinases and Phosphatidic Acid Phosphatases <i>M K Topham</i>	659
Disulfide Bond Formation <i>H F Gilbert</i>	664

VOLUME 2

DNA Base Excision Repair Pathways <i>R A O Bennett and B Dimple</i>	1
DNA Damage: Alkylation <i>J L Tubbs and J A Tainer</i>	9
DNA Glycosylases: Mechanisms <i>A C Drohat and A Maiti</i>	16
DNA Helicases: Hexameric Enzyme Action <i>D Sen and S S Patel</i>	21
DNA Ligases: Mechanism and Functions <i>A E Tomkinson and J A Della-Maria</i>	28
DNA Ligases: Structures <i>J M Pascal</i>	33
DNA Methyltransferases: Eubacterial GATC <i>M G Marinus</i>	40
DNA Mismatch Repair and Homologous Recombination <i>I Matic</i>	45
DNA Mismatch Repair and the DNA Damage Response <i>G-M Li</i>	51
DNA Mismatch Repair in Bacteria <i>A-L Lu</i>	54
DNA Mismatch Repair in Disease and Aging <i>P Hsieh</i>	60
DNA Mismatch Repair in Mammals <i>A J Phys and E Alani</i>	66
DNA Modification, Restriction Endonucleases: Type I Enzymes <i>D T F Dryden and G A Roberts</i>	72
DNA Oxidation <i>D O Zharkov</i>	77
DNA Polymerase β , Eukaryotic <i>W A Beard and S H Wilson</i>	82
DNA Polymerase I, Bacterial <i>C M Joyce</i>	87
DNA Polymerase III, Bacterial <i>H Maki and A Furukohri</i>	92
DNA Polymerases: Kinetics and Mechanism <i>K A Johnson</i>	96
DNA Polymerases: Reverse Transcriptase Integrase, and Retrovirus Replication <i>M-L Andréola, V Parissi, and S Litvak</i>	101
DNA Replication: Eukaryotic Origins and the Origin Recognition Complex <i>I Chesnokov and A Svitin</i>	108
DNA Replication Fork, Bacterial <i>M M Spiering and S J Benkovic</i>	114

DNA Replication Fork, Eukaryotic <i>L M Kelman and Z Kelman</i>	118
DNA Replication: Initiation in Bacteria <i>J M Kaguni</i>	121
DNA Replication, Mitochondrial <i>D A Clayton</i>	126
DNA Restriction and Modification: Type II Enzymes <i>S E Halford</i>	130
DNA Restriction and Modification: Type III Enzymes <i>D N Rao and S Bheemanaik</i>	136
DNA Secondary Structure <i>A Bacolla, K M Vasquez, and R D Wells</i>	142
DNA Sequence Recognition by Proteins <i>K Rutherford and G D Van Duyne</i>	149
DNA Supercoiling <i>T-S Hsieh</i>	154
DNA Topoisomerases: Type I <i>J J Champoux</i>	157
DNA Topoisomerases: Type II <i>A C Gentry and N Osheroff</i>	163
Dopamine Receptors <i>K A Neve</i>	169

Glossary

AAA proteins A protein family of oligomeric ATPases with diverse cellular activities.

AAA+ proteins A superfamily that encompasses, among other families, the AAA proteins.

Arginine finger A conserved arginine residue in the SRH that points into the nucleotide-binding pocket.

Clade A group of organisms or molecules, whose members share homologous features derived from a common ancestor.

Cluster analysis A data analysis tool for solving classification problems. Organisms or molecules are sorted into clusters, so that the degree of association is strong between members of the same and weak between members

of different clusters. Each cluster thus describes the class to which its members belong.

P-loop NTPases Nucleotidases that are characterized by the presence of a loop element that is associated with the phosphates of bound nucleotides.

Second region of homology (SRH) A hallmark of the AAA family. It is a conserved sequence region containing sensor 1 residue and arginine finger.

Sensor 1 and 2 Conserved amino acid residues in AAA+ proteins that contact bound nucleotide; sensor 1 is a polar residue, sensor 2 typically arginine.

Walker A and B motifs Consensus sequence elements that are characteristic of nucleotide-binding folds.

AAA Proteins

Complex cellular events commonly depend on the activity of molecular machines that efficiently couple enzymatic and regulatory functions within a multiprotein assembly. As these functions require energy, adenosine triphosphatases (ATPases) are often found as integral components in these assemblies. All ATPases harness energy gained from breaking the γ -phosphate bond of ATP. An essential and expanding subset in the areas of protein remodeling and quality control comprises proteins of the AAA family.

Structure and Mechanism of Action

AAA proteins, which belong to the superfamily of P-loop nucleoside triphosphatases (NTPases), share the common feature of a highly conserved, extended nucleotidase domain containing 200–250 residues. This so-called AAA domain is formed by two subdomains, an amino-terminal nucleotide-binding subdomain and a smaller carboxy-terminal helical subdomain. Comparison to the structures of other AAA+ proteins reveals that this subdomain arrangement represents the common structural core of the AAA+ superfamily (see later).

The nucleotide-binding subdomain contains two classical Walker A (GX4GKT) and Walker B (HyDE) motifs, which are involved in binding of the triphosphate moiety of the

nucleotide and coordination of a Mg^{2+} -ion, which is important for subsequent hydrolysis of ATP. It is a RecA-like, three-layered $\alpha\beta\gamma$ structure with a central five-stranded, parallel β sheet. The property that separates this fold from that of all other P-loop NTPases is the insertion of a β strand which results in the addition of a conserved polar residue to the active site. The residue has been named sensor-1 for the fact that it contacts the γ -phosphate of the bound nucleotide and is thought to discriminate between ATP and ADP. Indeed, mutagenesis of this residue highlights its critical role in cooperative ATP hydrolysis. The so-called second region of homology (SRH), in which sensor-1 lies, is the hallmark of the AAA family and makes it distinguishable from the larger and more diverse superfamily of AAA+ proteins.

The carboxy-terminal subdomain is largely helical and shows substantially greater structural variation, although it invariably occupies a similar position, diagonally above the base of the bound nucleotide. A recurring feature of this subdomain is a residue (typically arginine), called sensor-2 for its ability to interact with the nucleotide. Depending on the subtype of AAA proteins, either one or two AAA domains (D1 and D2) are present. In some proteins with two domains, both are evolutionarily well conserved (like in Cdc48p/p97); in others, either the D2 domain (like in Pex1p and Pex6p) or the D1 domain (in Sec18p/NSF) is better conserved.

AAA proteins assemble into oligomers, which form ring-shaped structures with a rather narrow central pore. These

oligomers are typically hexameric, although in a few cases, heptameric forms have also been proposed. Depending on the respective protein, the inter-subunit contacts that mediate assembly can lie either in the N-domain (see later) or the AAA domain or both. Some members with two AAA domains have dedicated one domain for the purpose of maintaining the structural stability and integrity of the oligomeric complex, such as D1 in p97/Cdc48p or D2 in Sec18/NSF. These domains are degenerate and have lost their ability to hydrolyze ATP. In addition to the physiologically active hexameric form, some AAA proteins, like katanin, do exist also as dimers, which assemble into rings in the presence of substrate proteins or regulatory cofactors. Further oligomerization to dodecameric complexes was also noticed for some proteins, but the physiological relevance of dodecamers remains unclear.

Several crystal structures of AAA proteins have been determined, among them the complete structure of p97, an ATPase with two canonical AAA domains (Figure 1). These structures have shown that in the hexameric conformation, the ATP-binding site is positioned at the interface between subunits, such that the SRH bridges the space between nucleotide-binding pockets of adjacent subunits. Whereas the sensor-1 residue of one subunit points into its own pocket, the conserved arginine residue (the so-called arginine finger) points into the next pocket in the ring (Figure 2). This observation has suggested a mechanism for concerted nucleotide hydrolysis, in which loss of the γ -phosphate in one binding site is conveyed to the next active site via rigid-body motion of the helix connecting the sensor-1 and arginine finger residues. It also provides an explanation for the high degree of sequence conservation in the SRH. Interestingly, the meiotic clade of the AAA family and some minor clades (see later), are characterized by a two-residue deletion in the SRH immediately preceding the arginine finger.

Amino-terminally to the AAA domains are non-ATPase domains (N-domains) which are involved in substrate binding and recognition. Divergence in the function of the various family members occurs to a large part from the wide variety of N-domains that are found. These domains act as tool heads interacting with substrates, either directly or through adaptor molecules. Upon ATP binding and hydrolysis, AAA proteins undergo conformational changes in the AAA domains that are registered in the N-domains. The result is a repositioning of the N-domains in the ring relative to each other and to the AAA domains. Motions in the N-domains can be transmitted as mechanical force to a bound substrate, resulting, for example, in remodeling or dissociation of a protein complex, or in the complete unfolding of a polypeptide chain and its subsequent translocation through the central pore of the AAA protein ring. In a sense, AAA proteins use the AAA module like a chemo-mechanical converter (motor) powered by ATP hydrolysis to energize such a mechanical force. The conserved features of AAA domains imply a common mechanism for the operation of the motor. Yet, small differences in nucleotide-sensing residues, in the domains attached to the motor or in the connecting regions between these parts, may determine the direction and timing of the forces that are exerted. They may also

Figure 1 Crystal structure of a representative AAA protein with two ATPase domains, mouse p97. The domains are colored in their succession from amino- to carboxy terminus: N-domain blue, D1 P-loop subdomain green, D1 helical subdomain yellow, D2 P-loop subdomain orange, D2 helical subdomain red. The top panel shows a top view and the middle panel a side view of the complex. The bottom panel illustrates schematically the succession of N, D1, and D2 domains in the polypeptide chain, as well as an enlargement of one of the D domains with the salient sequence motifs labeled.

affect substrate specificity of these proteins. Sequence divergence in the AAA domains, acquisition of different N-domains, followed by gene duplication in case of proteins with two AAA domains, have thus produced an array of biological activities from a common ancestral protein.

Figure 2 Enlarged, cut-away view of three consecutive nucleotide-binding sites in the p97 ring. Only the structural elements needed to illustrate the communication between active sites are shown. The residues participating in nucleotide binding and hydrolysis are labeled and color coded as in **Figure 1**. (Note that most AAA proteins, including p97 depicted here, lack a sensor-2 arginine.)

Table 1 Examples of AAA proteins (upper part) and AAA+ proteins (lower part) involved in cell biological processes

Protein	Function	Cellular location
PAN, ARC, Rpt1-Rpt6	Accessory factors to the proteasome in archaea, bacteria, and eukaryotes; unfolding and translocation of proteins	Cytosol
Pex1 and Pex6	Dislocation of PTS receptor from the peroxisomal membrane for recycling in the cytosol	Peroxisome and cytosol
NSF	Disassembly of SNARE complexes for vesicular transport	Cytosol, vesicles, Golgi, and endosomes
Vps4	Disassembly of ESCRT-III complex during budding into multivesicular bodies; related function in archaea?	Multivesicular body and endosomes in eukaryotes; cytosol in archaea
Cdc48p/p97	Retranslocation of misfolded proteins during ERAD, nuclear envelope, and Golgi reassembly after mitosis; archaeal VAT homologs with possible function in protein quality control	Cytosol, endoplasmic reticulum, Golgi
FtsH	Metalloprotease; degradation of misfolded membrane proteins	Inner membrane of bacteria and endosymbiotic organelles
i-AAA and m-AAA proteases	Maturation of mitochondrial proteins and mitochondrial protein quality control	Mitochondrial inner membrane
Katanin	Microtubule severing	Centrosome and spindle
BCS1	Formation of Rieske iron–sulfur cluster proteins	Mitochondrial inner membrane
Dynein	Minus-end-directed microtubule-based motor protein	Microtubules, spindle, vesicles
Lon	Protease; degradation of short-lived and misfolded proteins	Organelles and bacterial cytosol
Clp/Hsp100	Protein quality control in conjunction with proteases, disaggregation, and unfolding of proteins	Cytosol
DnaA	Initiation of chromosomal replication in bacteria, promotion of local DNA unwinding within the replication origin	Bacterial cytosol
RuvB clamp loader	Branch migration helicase in DNA recombination	Bacterial cytosol
Bchl	Component of magnesium chelatase complex involved in chlorophyll synthesis	Plastids and bacterial cytosol

Classification and Evolution: AAA and AAA+ (Super)Families

The classical AAA family is part of the AAA+ superfamily of ATPases that includes also a number of more distantly related cellular regulators. This superfamily has an expanded activity spectrum compared to the core AAA family (**Table 1**). AAA+

proteins are involved in protein degradation, membrane fusion, DNA replication, microtubule dynamics, intracellular transport, flagellar and ciliary beating, and disassembly of protein complexes and protein aggregates. Notably, some proteins like DnaA and RuvB interact with DNA. In their case, mechanical force results in the unwinding of the nucleic acid rather than unfolding of a protein.

The classification of AAA proteins is based on the analysis of their AAA domains. Several approaches have been used to compute phylogenies for AAA proteins, differing in the data available at the time (i.e., sequenced genomes) and in the inclusion of degenerate, inactive, and/or rapidly evolving sequences. More recently, cluster analysis has been applied toward the same goal. A cluster map of the AAA+ superfamily yields a well defined and compact group for AAA proteins, whose substructure can be further analyzed either by clustering at more stringent cutoffs or by classical phylogenetic methods. This approach outlines six major clades of AAA domains, namely proteasome subunits, metalloproteases, domains D1 and D2 of ATPases with two AAA domains, the meiotic group with MSP1/katanin/spastin, and BCS1 and its homologs, as well as a number of minor clades (Figure 3). Although deep branching, two of these minor clades are located next to major clades: ARC (AAA ATPase forming ring-shaped complexes)

next to the D1 and D2 clade, and a group of methanogenic sequences next to the metalloproteases, named AMA for its occurrence in *Archaeoglobus fulgidus* and methanogenic archaea. Most of the minor clades close to the root have gapped SRH regions and are similar to the AAA+ proteins in the positions of the conserved arginine finger residues, which may indicate an ancestral trait of these sequences. Clear clustering of the eukaryotic clades and predominance of prokaryotic sequences in deep-branching clades suggest that the AAA family had already reached most of its diversity before the three domains of life separated.

As mentioned above, the N-domains of the AAA proteins are crucial for substrate specificity and consequently for the cellular function of the respective AAA protein. A cluster analysis of N-domains resolves these sequences into 20 groups. This implies that the wide variety of biological functions of these proteins originates primarily from divergence in their

Figure 3 Phylogenetic tree of AAA proteins.

N-domains. Some of these differences were acquired after the division into plants and other eukaryotes (fungi and animals) as observed in the BCS1 clade. Other family members show high divergence in their N-domains although their AAA domains are of obvious monophyletic origin, suggesting an evolutionary exchange or recruitment of N-domains (like smallminded and Yta7 in the D1 clade). Interestingly, there are also N-domain homologies between the CDC48p/p97 group and the deep-branching AMA group as well as between ARC and proteasomal ATPases. Sequence analysis of N-domains of AMA proteins using PSI-Blast led to the assumption that these proteins adopt a structure similar to the β -clam fold found in N-domains of the CDC48p/p97 group. The homology between ARC and PAN proteins was proposed earlier mainly because of the presence of a coiled-coil region at the very end of the N-domains and of a similar genomic context (proteasome loci). Subsequent crystallographic and biochemical characterization of ARC indicated that it possesses indeed structural similarity to PAN. This similarity extends to function; ARC interacts with bacterial proteasomes and is thought to funnel unfolded substrates into the proteasomal ring chamber for proteolysis (see later for more details). This example demonstrates the usefulness of phylogenetic trees for gaining insight into possible biological functions of as yet uncharacterized members of the AAA protein family.

Cellular Functions of AAA Proteins

Members of the AAA family are found in all three organismal kingdoms and they are essential for many cellular processes (see Table 1). To showcase the functional diversity of this protein family, the following sections provide three important examples of well-characterized AAA proteins.

Mediating-Protein Degradation by the Proteasome

The proteasome forms the core of the protein quality control system in archaea and eukaryotes and also occurs in one bacterial lineage, the Actinobacteria. AAA proteins are destined as accessory factors of proteasomes, as they can use the energy from ATP hydrolysis to unfold potential protease substrates and transfer them into the interior of the associated proteasomal cylinder for degradation. The AAA proteins in the proteasome subunit clade form homo-oligomeric complexes in archaea and hetero-oligomeric complexes in eukaryotes. In eukaryotes, six distinct monomers form a hexameric ring that acts as an unfoldase and de-ubiquitinates tagged proteins prior to threading them through the proteasome for digestion. It appears that the different AAA proteins within a proteasome aid in the recognition and degradation of different subsets of proteins. The N-domains of the archaeal proteasomal ATPase proteasome-activating nucleotidase (PAN) and of its actinobacterial homolog, ARC or Mpa, form hexameric rings, whose identical subunits consist of an amino-terminal coiled coil and a carboxy-terminal OB domain. In ARC-N, the OB domains are duplicated and form separate rings. Detached from the ATPase domains, PAN-N and ARC-N can act as chaperones, demonstrating their general ability to interact with denatured polypeptides. It has been suggested that, in the context of the entire AAA protein, concerted radial

motions of the coiled coils relative to the OB rings are crucial for unfolding and/or translocation of the bound polypeptide chain through the pore of the ring. The process that determines which proteins eventually become substrates for the unfoldases and subsequently for the proteasome is still unknown. At least for a range of proteins, however, dedicated coupling factors do exist. Similar to eukaryotic ubiquitin, which tags proteins for degradation, small tagging factors have been found in archaea (SAMP) and actinomycetes (Pup). Pup has been shown to interact with the coiled coils of ARC, thereby recruiting any conjugated protein to the unfoldase.

Cdc48p/p97 is perhaps the best-studied AAA protein. It has also been implicated in proteasome-dependent protein degradation, but belongs to a different clade than the above-described proteins (see Figure 3). In eukaryotes, misfolded secretory proteins are exported from the endoplasmic reticulum (ER) and degraded by the ER-associated degradation pathway (ERAD). Nonfunctional membrane and luminal proteins are extracted from the ER and degraded in the cytosol by proteasomes. Substrate retrotranslocation and extraction is assisted by Cdc48p in complex with its adapter proteins Ufd1p and Npl4p on the cytosolic side of the membrane. Once it emerges on the cytosolic side, the substrate is ubiquitinated by ER-based E2 and E3 conjugating enzymes before degradation by the proteasome. The ancestral function of Cdc48p must lie somewhere else, though. Highly conserved homologs (named VAT) are found in archaea, in some organisms even as multiple variants. VATs may play a role in archaeal protein quality control, possibly in conjunction with the proteasome. Their ability to handle misfolded proteins could have made them well suited to adapt to new functions during the evolution of the eukaryotic cell.

Membrane Fusion and Vesicle Transport

Several AAA proteins seem to have a central role in reshaping cellular membranes. These include the originally defined AAA proteins with two ATPase domains in the D1 and D2 clade, namely Sec18/NSF, Pex1 and Pex6, YTA7, SPAF, and smallminded. Vesicular transport requires cargo selection and vesicle production through a budding process. The subsequent vesicle transport and targeting process concludes with specific membrane fusion of the vesicle to its target membrane. Early molecular analysis of vesicular trafficking between Golgi cisternae identified an essential *N*-ethyl-maleimide-sensitive factor (NSF). It functions as a soluble NSF attachment protein (SNAP) receptor (SNARE) dissociation factor. Aided by SNAPs, it binds to SNARE complexes and utilizes the energy of ATP hydrolysis to disassemble them, thus facilitating SNARE recycling.

A related process is mediated by vacuolar protein sorting 4 (Vps4), a protein involved in endosomal transport through multivesicular bodies. These bodies are endosomal compartments in eukaryotes where ubiquitinated membrane proteins are sorted into specific vesicles. This process involves the sequential action of three multiprotein complexes, ESCRT I–III (ESCRT standing for endosomal sorting complexes required for transport). Vps4p is anchored to the endosomal membrane and has been shown to catalyze the dissociation of ESCRT complexes. Assembly of Vps4p itself is assisted by the conserved Vta1p protein, which regulates its oligomerization

status and ATPase activity. Bioinformatic analysis has shown Vps4p and ESCRT homologs in archaea, pointing to the existence of a rudimentary mechanism for vesicle transport and membrane invagination. As archaea do not have elaborate intracellular membrane systems, the exact cellular role of these membrane-sculpting processes remains to be discovered.

Vps4 belongs to the meiotic clade of the AAA family, which derives its name from its member katanin, a microtubule severing protein implicated in mitosis and meiosis. Spastin, another member of this group, is involved in microtubule disassembly.

AAA Proteins As Membrane-Bound Metalloproteases

Proteins in the metalloprotease group are distinguished by a unique domain structure, with an extracellular N-domain, connected by a transmembrane helix to an AAA domain and a carboxy-terminal metalloprotease domain. They are found in the inner membranes of bacteria, where they degrade both soluble and membrane proteins, and in endosymbiont-derived organelles, where they primarily degrade unassembled subunits of membrane complexes. In the latter, they occur as two distinct complexes, one of which has an inverted orientation in the membrane.

The paradigm for the metalloprotease group is FtsH, the only essential protease of *Escherichia coli*. It forms a homo-hexamer, which, at least in some species, is further complexed with an oligomer of the periplasmic, membrane-bound modulating factor HflKC. FtsH is a processive endopeptidase and degrades certain misassembled membrane proteins, as well as a set of short-lived proteins, thereby enabling cellular regulation at the level of protein stability. Although the details of substrate recognition are largely unknown, the ATPase module is thought to be crucial for the ability of FtsH to dislocate membrane protein substrates out of the membrane and to translocate them to the metalloprotease domain. FtsH, thus, turns out to be an intriguing case of an AAA protein, where translocase activity and proteolytic function are integrated as successive modules into one polypeptide chain.

Conclusions

The function of several AAA family members has been well delineated by now and protein unfolding and disassembly emerges as a common mechanistic theme. An increasing number of high-resolution structural studies have provided a detailed picture of the conserved structure of the AAA domain. How these domains assemble into functional oligomers and change their conformation during ATP hydrolysis to generate movement and mechanical force has been studied less extensively. Which are the approaches likely to advance our knowledge in this area? High-resolution structures of oligomeric complexes in different nucleotide-bound states, and eventually

bound to substrates and/or cofactors, will enable a better molecular understanding of the inner workings of AAA proteins. To determine the precise function and mechanism of action of a particular ATPase, reconstitution of its reaction *in vitro* with purified components remains an essential step. Results from such studies would also shed more light on the fact that there is no strict correlation between AAA protein subtypes and clades on the one side, and a specific function and activity on the other side. This suggests that early in the evolution of AAA, there was a small number of subtypes that subsequently expanded and adapted to allow the processing of a wide variety of targets.

Another aspect gaining importance concerns the nature of disease mutations in AAA proteins, of which there is a growing number. Interestingly, some autosomal dominant diseases, such as hereditary spastic paraplegia (spastin defect), and some autosomal recessive diseases, such as mitochondrial complex III deficiency (BCS1 defect), are both caused by mutations in the AAA domain that are thought to affect ATP binding and hydrolysis; it is not clear whether for autosomal dominant diseases, the mutations act as dominant negatives. A thorough dissection of the generic AAA ATPase reaction cycle would, therefore, be beneficial for this research area as well.

Glossary

ABC1 Specific small amino acid sequence which is a specific signature of ABC proteins.

C-, D-, H-, P-, and Q-loop Loops are located at the junction of α -helices and are represented by conserved amino acid residue in one letter code: C is cysteine, D is aspartate, H is histidine, P is proline, and Q is asparagine.

NBD Nucleotide-binding domain of about 100 amino acids which is characterized by a Walker A and Walker B motif.

Pdr5p The major yeast ABC transporter involved in pleiotropic drug resistance including the azole-antifungals.

P-gp The major ABC transporter (glycoprotein) involved in mammalian multidrug resistance

and which is often activated during cancer chemotherapy.

Transmembrane span (TMS) and transmembrane domain (TMD) The existence of the transmembrane span is predicted by frequency of hydrophobic residues in a reading window of about 17 amino acids. In ABC transporters, the transmembrane domains usually comprise six contiguous transmembrane spans.

Transporter classification (TC) Classification of over 1000 transporter families, developed by Milton Saier based on a combination of mechanistic and phylogenetic criteria.

Walker A and B Small consensus of amino acid sequences involved in ATP binding.

The ABCs constitute the largest family of proteins. They are present in all living species from *Archaea* to *Homo sapiens*. They make up to 4% of the full genome complement of bacteria such as *Escherichia coli* or *Bacillus subtilis*. Each eukaryote genome contains several dozens of ABC proteins. They are recognized by a consensus nucleotide-binding domain (NBD) of approximately 100 amino acids which comprises a series of structural and sequence motifs illustrated in **Figure 1**: the Walker A motif, the ABC1 signature, the Walker B motif, the Helical domain, and the P, Q-, C-, D-, and H-loops which are structural junctions between α -helices marked by a conserved proline, asparagine, cysteine, aspartate, or histidine residue. The ABC proteins catalyze a wide variety of physiological functions, many but not all of which are related to transport. We wish to describe the major physiological and biochemical functions as well as the structural properties of some of the best-known ABC transporters using as examples the multidrug exporters Sav1866 from *Staphylococcus aureus*, Pdr5p from *Saccharomyces cerevisiae*, and P-gp from *H. sapiens*.

Topology

Each ABC transporter molecule contains, or is associated to, one or two cytoplasmic adenosine triphosphate (ATP)-binding domains named NBDs and one or two transmembrane domains (TMDs). Each TMD comprises usually six transmembrane spans (TMSs) separated by the three extracytoplasmic loops ECL1, ECL2, and ECL3 and the two intracytoplasmic loops ICL2 and ICL3. Association of one TMD to one NBD results in a half-size ABC transporter, which functions as homo- or heterodimers so that the minimal functional organization of an ABC transporter is considered to be TMD–NBD/TMD–NBD or NBD–TMD/NBD–TMD. In bacteria, two NBDs

often associate with two TMDs either as four single subunits encoded within the same operon or in various combinations of fused subunits (**Figure 2**). Association of other proteins may occur. The most prominent associated bacterial protein is the periplasmic solute-binding receptor, which in Gram-negative bacteria is found in the periplasm, and in Gram-positive bacteria is often a lipoprotein bound to the external membrane surface via electrostatic interactions. The three domains of the bacterial ABC uptake transporters, namely the periplasmic-binding receptor, the cytoplasmic NBD, and the membrane TMD, are believed to have arisen from a common ancestral ABC transporter in which these three proteins were already present. However, during evolution the sequence of the periplasmic solute-binding receptors diverged more rapidly than that of the TMDs while that of NBDs remained the least divergent. Thus, all NBDs are homologous, but this is not true for the TMDs or the receptors.

In eukaryotes, two TMDs and two NBDs are often, but not always, associated in one single molecule called ‘full-sized ABC transporter’. The topological relation between NBDs and TMDs is variable (**Figure 3**); additional TM spans occur in some systems as well as extracytoplasmic domains of presumed regulatory function.

Phylogeny

The different families of ABC proteins transport a wide variety of substrates against their concentration gradient using the energy of ATP hydrolysis carried out by NBD. In bacteria, the transported substrates are either imported in or exported out of the cell. In eukaryotes, only extracytoplasmic exporters transporting substrates either out of the cell or into organelles are known. Within the ABC transporters, a total of 173

Figure 1 Example of topological relations between nucleotide-binding domains (NBDs) and transmembrane domains (TMDs) in full-sized and half-sized ABC transporters.

Figure 2 Example of protein subunits constituting bacterial ABC influx transporters.

phylogenetic families have been identified so far and classified within the transporter classification (TC) system developed by Milton Saier in San Diego. These families generally correlate with substrate specificity and comprise both efflux and influx transporters.

Since 1995, the *in silico* analysis of hundreds of full genome sequences has allowed the identification of thousands of new ABC proteins. For instance, within the 49 ABC proteins identified in the human genome, five major families of transporters have been identified and named ABCA (or ABC1), ABCB (or MDR including the famous P-gp described below), ABCC (or MRP), ABCD (or ALD), and ABCG (or WHITE). This classification overlaps with the TC.

S. cerevisiae genome contains 32 ABC proteins among which 22 are associated to TMDs. The largest yeast ABC family is Pdrp identified in 1997 by Anabelle Decottignies and André Goffeau and shown later to be present in all fungi and plants.

Figure 3 Reconstructed structure of the purified yeast Pdr5p reconstituted in lipid-containing particles and observed by cryo electron microscopy.

This family is not detected in the animal kingdom. Conversely, the large human and mouse ABCA family identified in 1994 by Giovanna Chimini is not represented in fungal genomes.

Function and Diseases

The ABC transporters from Archaea, Gram-negative, and Gram-positive plasma membranes are widely different in their organization and composition. The variety of substrates transported: sugars, amino acids, lipids, ions, polysaccharides, peptides, proteins, toxins, drugs, antibiotics, xenobiotics, and other metabolites is reflected by the divergence of the periplasmic sensor and that of the TMD which control the specificity and the direction (efflux or influx) of transport.

Even if all eukaryotic ABC transporters are effluxers that comprise each a TMD fused to NBD, some of them are not directly involved in moving substrates. For instance, in the cystic fibrosis transmembrane regulator (CFTR) and in the sulfonyleurea receptor (SUR), the hydrolysis of ATP appears to be linked to the regulation of opening and closing of ion channels carried by the ABC protein itself or other proteins. The presence of NBD and TMD in all ABC transporters, however, suggests that a basic coupling mechanism exists for efflux and influx whatever the transported substrate. However, distantly related proteins utilize an NBD to drive diverse nontransport processes such as DNA repair or protein elongation or regulation of RNase activities.

One strong impetus for the study of mammalian ABC transporters is their involvement in human diseases. Many mendelian diseases and complex genetic disorders are caused by ABC transporters including cystic fibrosis, adrenoleukodystrophy, Stargardt disease, Tangier disease, immune deficiencies, progressive familial intrahepatic cholestasis, Dublin-Johnson syndrome, Pseudoxanthoma elasticum, persistent hyperinsulinemic hypoglycemia of infancy due to focal adenomatous hyperplasia, X-linked sideroblastosis and anemia, age-related macular degeneration, familial hypoapoproteinemia, fundus flavimaculatus, retinitis pigmentosa, and cone rod dystrophy. Frequent cases of resistance to plant, fungal, or mammalian pathogens and to chemotherapeutic treatments of cancers often result from induction or activation mutations of pleiotropic drug resistance (Pdrp), multiple drug resistance (MDR), or multidrug resistance-related protein (MRP) transporters. Basic

studies of human, plants, or pathogen ABC transporters would greatly benefit from heterologous expression of human ABC transporter genes in yeast or other cells but this technology is not fully satisfactory yet. Meanwhile, knockout technology in the mouse allows physiological analysis of the mammalian transporters.

Structure and Biochemical Mechanism

In 2010, over a dozen high-resolution X-ray structures of functional ABC transporters are available and have contributed to the emergence of a consensus view of the catalytic mechanism of transport. Recent analyses at the electron microscopy level of purified bacterial (BmrA from *B. subtilis*) and a fungal (Pdr5p from *S. cerevisiae*) drug efflux ABC transporter came to a remarkably coherent set of conclusions. In both cases, the basic structural unit seems to comprise four joining NBDs that correspond to two full-size Pdr5p or four half-size BmrA. The NBD are related to the TMDs through four distinct stalks. Each NBD is oriented at a fixed 90° angle relative to its neighbor NBDs. This raises the possibility of concerted rotation movements of the NBDs implying a certain flexibility of the stalks. No intramolecular or no intramembrane pores were observed even though there is room (or chamber) between the four stalks that join together at their NBD tips (Figure 4).

The nature of the stalks, TMD and NBD, was further identified by the analysis of the well-resolved structure of complete dimeric ABC bacterial and eukaryote transporters such as those obtained for the phospholipid flippase MsbA from *E. coli* and *Staphylococcus typhimurum*, the vitamin B12 importer BtuCD from *E. coli*, the importer of metal-chelate H11470/1 from *Haemophilus influenzae*, the drug exporter Sav1866 from *S. aureus*, and the mammalian multidrug exporter P-gp.

The folds of the membrane and stalk domains were found to be dissimilar in the different structures analyzed so far. This may not be surprising taking into account the different species analyzed, the different cocrystallized ligands, the different numbers of TMS, and the different functions of the proteins analyzed. In particular, the communication between the NBD and the TMD was found to be variable and, for instance, is carried out either through a long and complex intracytoplasmic loop (ICL) in MsbA, through a short L-shaped ICL between

the transmembrane spans 6 and 7 in BtuCD, or through the ICL3 and ICL 6 in Sav1866.

A clear contribution of the X-ray structures is the observation that two molecules of ATP are bound at the interface of the two NBDs. Each nucleotide-binding site comprises a Walker A motif from one monomer and the ABC1 C motif from the other monomer in a head-to-tail arrangement of the two interacting NBD monomers.

As the folds of the various ABC transporters are highly variable we focus on some basic structural properties of the bacterial Sav1866 and the mammalian P-gp multidrug drug exporters which have been reported, respectively, by Kaspar Locher in 2006 and Goffrey Chang in 2009.

The homodimeric Sav1866 transporter has two identical subunits, each comprising a NBD fused to a TMD made of six transmembrane α -helices. It exports a wide series of unrelated drugs such as the anticancer compounds doxorubicin and vinblastin. Two coupling α -helices, located in ICL3 and ICL6, interact with grooves from the two NBDs. This structural motif is conserved in all ABC transporters but its amino acid sequence is not conserved. Individual TMS from the two TMDs embrace each other and form two symmetric membrane bundles each made of six mixed TMS comprising two membrane α -helices from one TMD and four membrane α -helices from the other TMD. A central cavity was identified between the TMDs. As it faces outward, it was interpreted to represent an open drug extrusion pocket.

P-gp is a full size NBD–TMD–NBD–TMD transporter which is responsible for multiple drug resistance of mouse and human cell and to which has been attributed failure of chemo-treated cancer patients. The mouse P-gp was expressed in the yeast *Pichia pastoris*, purified and crystallized. This 3.8 Å structure is a nucleotide-free, inward conformation arranged in two symmetric halves each comprising an NBD and a TM bundle. Each TM bundle comprises six mixed TMS in which spans from the two TMDs embrace each other. A large drug-binding pocket of about 6000 cubic Å located at the intersection of the two TM bundles is open to both the inner membrane leaflet and the cytoplasm. A total of 73 amino acids' aromatic and hydrophobic residues facing this cavity was accessible to solvent and involved in the overlapping binding of three different ABC inhibitors. Only two amino acid residues are common to the three binding sites. Two portals are wide open to the inner

Figure 4 The consensus adenosine triphosphate (ATP)-binding region of a typical ABC protein is made of approximately 100 amino acids (aa), including the Walker A motif, the ABC1 signature, the Walker B motif, the helical domain, and the P-, Q-, C-, D-, and H-loops (see section Glossary).

phospholipid bilayer and allow entry of hydrophobic drugs which penetrate the membrane by passive diffusion.

Transport Mechanism

Recent structural observations have led to the disposal of the early hypothetic mechanism of alternating ATP-binding sites during the drug transport cycle. Instead, a consensus emerges favoring a rather simple alternating outward-inward access mechanism by which binding and hydrolysis of ATP by the cytoplasmic NBD controls the binding and translocation of the ligand through the TMD (Figure 5). Ligand binding to a high-affinity pocket formed by the TMDs induces a conformational change in the NBDs resulting in a higher affinity for ATP. Two molecules of ATP each binding to both NBDs induce a close dimeric conformation which promotes the extrusion of the ligand. ATP hydrolysis triggers the opening of the NBD dimer. Finally, phosphate and ADP are released and the ligand-free NBD dimer conformation is restored.

This two-state alternating access mechanism is shared not only by eukaryotic drug exporters but also by bacterial importers. This is shown by analyses of the type 1 bacterial importers such as the maltose (MalFGK), histidine (HisPQM), and methionine (MetNid/I) importers in which low-affinity substrate-binding proteins mediate the delivery of substrates to the ATP-bound form and also of the type 2 bacterial importers, such as the vitamin B12 (BtuCD) and metal-chelate (Hi1470/1) importers which involve a binding protein of high affinity for the substrate even in the absence of ATP. The delivery of substrates via a binding protein introduces an additional conformational switch that is of appreciable structural and mechanistic divergences between type 1 and type 2 importers.

The multiple conformation changes occurring during the ATP-driven substrate transport from prokaryotic and eukaryotic transporters are far from being unraveled; however, at present, it is best to regard the importers and the exporters as having partly distinct molecular mechanisms. Moreover, the

MDR family of mammalian ABC exporters may have mechanisms partially different from that of the Pdrp family of plant and fungal multidrug transporters. Obviously, the resolution of more complex mechanisms such as those involved in the gated chloride flux of CFTR, the regulation of the potassium channel of SUR1, or the loading of antigenic peptide by TAP1 will have to wait until more structural and biochemical information become available.

Substrate Specificity of the Multidrug Exporters and Reversal Agents

One of the most intriguing contemporary biochemical problems is the characterization of the interactions of the TMDs with their transported substrate. The most extraordinary feature in this context is the apparent lack of specificity of the yeast Pdr5p and human Pgp that transports hundreds of different chemicals, apparently contradicting the famous key/slot concept described in all textbooks. It is now recognized that at least three partly overlapping drug-binding sites operate in MDR, MRP, and Pdrp multidrug transporters and that drug binding depends on the hydrogen-bond acceptor properties, presence of aromatic rings, and hydrophobicity properties as well as on the surface volume of the substrates.

Since 1980, tremendous efforts have been made to identify inhibitors that can reverse MDR in cancer cells or Pdrp in fungi. Over 30 compounds with cabalistic names and structures have been shown to inhibit the cancer-related efflux pumps ABCB1 (MDR), ABCC1 (MRP), or ABCG2 (BCRP), or the fungal Pdrp transporters.

Such inhibitors may act directly by acting as pseudosubstrate, as competitive inhibitor of ATP binding or as a noncompetitive inhibitor acting at remote sites. They may also act indirectly on aspects of metabolism that affect efflux. The variety of identified drug pump inhibitors indicates that the development of efficient and specific inhibition of the anticancer and antifungal pumps should be possible. However, no

Figure 5 The flip-flop hypothesis for drug transport. Coupling between TMDs and NBDs is assured through conserved α -helices located in ICLs. The inward conformation of the TM bundles binds drugs in its cavity which is open both to the cytoplasm and to the inner phospholipid leaflet of the membrane. Upon binding of ATP, the NBDs dimerize and set the outward conformation in which the drug-binding site is exposed to the external milieu. ATP hydrolysis releases drugs, disrupts NBD dimerization, and resets the inward conformation.

ABC pump inhibitor is yet used clinically. Obviously, many pump inhibitors, such as the antimalarial quinine derivatives or the immunodepressor FK506 are known to act on diverse physiological functions. Moreover, ABC drug pumps seem to be involved in important physiological functions not related to drug efflux such as the development, differentiation, and maturation of immune cells. This may explain the multiple secondary effects of the inhibitors. One may expect that until the molecular structure and mechanisms of drug efflux are fully understood, the development of anti-MDR or Pdrp compounds will remain inefficient and merely based on brute screening. The ball is clearly in the hand of scientists studying basic mechanisms. However, some peculiar clinical treatments have been considered. For instance, low concentrations of isobuprofen, which is a potent anti-inflammatory drug, inhibits azole efflux from *Candida albicans*, and has been proposed for combination treatment of fungal infections with fluconazole.

In addition, alternative strategies such as regulating expression of drug transporters or uptake of anticancer drugs are also being considered.

Conclusion

The next frontiers in the study of ABC transporters are challenging. Many aspects of the evolutionary history of this large ubiquitous family are still to be unraveled. Better heterologous overexpression systems have to be developed to allow further biochemical and mechanistic studies. Additional atomic structures have to be produced to identify all conformation changes during the ATP-driven transport cycle. The diverse mechanisms

of ABC transporters in bacteria, fungi, plants, and animals have to be sorted out. Specific inhibitors of ABC drug importers and exporters have to be screened for. The physiological mechanisms of ABC-linked diseases have to be further studied in mouse knockouts. Systems prone to specific inhibition of ABC transporters expression by interfering RNA have to be explored. Genetic therapy of the ABC diseases has to be developed.

Glossary

Capping protein In theory, any protein that binds either the barbed or pointed end of actin filament and prevents monomer addition to that end. In practice, used to mean barbed-end-capping protein, and often heterodimeric capping protein in particular.

Critical concentration The concentration of monomers in a solution of actin at equilibrium between monomers and

filaments. Under polymerizing conditions, the critical concentration with both the barbed and pointed ends free is $\sim 0.1 \mu\text{M}$. When the barbed end is capped, the critical concentration rises to $0.5\text{--}0.7 \mu\text{M}$.

Sequestering protein Protein that binds actin monomer and prevents addition to either end of the filament. Neither profilin nor cofilin are sequestering proteins.

Actin is a monomeric protein that polymerizes into helical filaments. Apart from its role in muscle cells as a scaffold for myosin-based contraction, actin's function often depends on its ability to assemble into filaments from monomers rapidly and to disassemble equally rapidly. Actin alone can polymerize *in vitro*, but both the kinetics and equilibria of polymerization are controlled in cells by specific actin-binding proteins that serve to modify the assembly/disassembly cycle inherent to actin itself. Some actin-binding proteins of particular importance are sequestering proteins, profilin, capping protein, and ADF/cofilin.

Actin Structure

Actin Monomer Structures

Actin is a 43-kDa (375-amino-acid) globular monomer, which binds a nucleotide (adenosine triphosphate (ATP) or adenosine diphosphate (ADP) in cells) in a deep cleft between two halves of the protein (Figure 1(a)). The affinity of actin for nucleotide is greatly increased by divalent cation. Due to its relative cytosolic abundance (hundreds of micromolar), Mg^{2+} is the main actin-bound divalent cation in cells, but other cations, especially Ca^{2+} , are used for special purposes *in vitro*.

Actin Isoforms and Model Systems

Mammals contain six highly conserved actin isoforms, with at least 93% amino acid identity (Table 1). Actin from nonmammals is similarly conserved, with budding yeast 88% and *Acanthamoeba castellanii* 95% identical to human nonmuscle β -actin. Bacteria contain several proteins with some properties similar to actin, MreB, ParM, and Mbl.

Due to its ease of isolation, much of the biochemical data on actin assembly/disassembly are derived from studies of vertebrate muscle actin. Seminal studies on actin biochemistry were begun by Straub and Feuer during World War II using rabbit muscle actin. The sole actin isoform of budding yeast has also been a model, due to the combination of biochemistry and genetics in this system. Of the bacterial actin homologs, ParM is the most well characterized biochemically.

The highly similar sequences of actins from diverse eukaryotic species suggest that results in model systems will be close approximations for most actins. However, specific biochemical properties can vary between actins, such as affinities for some actin-binding proteins.

Individual cells can possess multiple actin isoforms simultaneously. Mammalian nonmuscle cells often contain both β - and γ -actin. The reasons behind this diversity are not well understood, but differential subcellular localization has been observed. Some unicellular organisms possess multiple actin isoforms. For instance, *Dictyostelium* has ~ 20 actin genes.

Actin Filaments

Actin filaments are right-handed two-stranded helices, with ~ 13 monomers per turn (Figure 1(b)). Each monomer adds $\sim 2.7 \text{ \AA}$ to the filament, so there are ~ 370 monomers per micron. All monomers are oriented in the same direction along the helix, making the filament polar. Due to the filament's arrow-like appearance when coated with myosin, the two ends are often called 'barbed' and 'pointed', respectively. The nucleotide-binding cleft faces the pointed end. Some refer to the barbed and pointed ends as '+' and '-', respectively.

Actin Dynamics

General Concepts in Actin Assembly/Disassembly

Under polymerizing conditions, actin monomers spontaneously polymerize into filaments, without need of other proteins. Polymerization from monomers can be divided into two processes: nucleation, whereby actin monomers assemble to form a trimeric nucleus, and elongation, whereby additional monomers add to this nucleus (Figure 2). Nucleation is highly unfavorable, with equilibrium dissociation constants in the millimolar range. Consequently, a major control point for cellular actin assembly is enhancement of nucleation rate. Elongation occurs rapidly at the barbed end (diffusion-limited on-rate) and 10-fold more slowly at the pointed end. For reasons explained later, pointed-end elongation rarely occurs in cells, and we will only consider barbed-end elongation in this article. While both

Figure 1 Structure of actin monomers and filaments. (a) Ribbon diagram of actin monomer backbone, oriented with the surface at the pointed end facing upward. NUC, nucleotide/divalent cation-binding pocket. N and C termini are indicated, as well as cysteine374, which is labeled by pyrene-iodoacetimide. (b) Atomic models of three actin monomers fit into a three-dimensional reconstruction of an actin filament obtained by electron microscopy and image analysis. Mg-ATP and Mg-ADP monomers can nucleate and elongate, Mg-ATP monomers do both faster. Upon adding to filaments, monomers are referred to as 'subunits'.

Monomers hydrolyze ATP extremely slowly. Upon adding to a filament, the hydrolysis rate increases to $\sim 0.3 \text{ s}^{-1}$. With a reasonable concentration of ATP-actin monomers, ATP hydrolysis occurs more slowly than elongation, which occurs at $10 \mu\text{M}^{-1} \text{ s}^{-1}$. Thus, a 'cap' of ATP-subunits builds up at the barbed end. Furthermore, the inorganic phosphate (Pi) hydrolysis product remains bound to the subunit for a considerable time before dissociating, while the ADP product remains tightly bound while the subunit remains on the filament. At steady state, three regions exist on an actin filament: ATP-subunits at the barbed end; ADP-Pi-subunits in the middle; and ADP-subunits toward the pointed end. As discussed later, Pi release is crucial to actin disassembly.

Subunits disassociate from both ends of a filament and do so more rapidly from the barbed end than from the pointed end. ADP-subunits release from the barbed end faster than ATP-subunits. Once released from the filament, the monomer slowly exchanges its ADP with ATP, assuming an excess of ATP in solution (which is the cellular situation).

Thus, actin assembly/disassembly occurs in a cycle (Figure 2). Nucleation occurs slowly, but filaments elongate rapidly once formed. Since barbed-end elongation is 10-fold faster than pointed-end elongation, and since ATP hydrolysis occurs slowly, ADP-subunits are at higher concentration toward the pointed end. Subunits dissociate from both ends and do so faster from the barbed end in both the ATP- and ADP-bound states. However, since monomer association is much more rapid at the barbed end, more net growth occurs at this end. Released ADP-monomers exchange ATP for ADP slowly (half-time $\sim 50 \text{ s}$).

Through this cycle, equilibrium between assembly and disassembly is reached, in which the concentrations of actin in filaments and as monomers become constant. When ATP is in constant supply (and assuming an excess of Mg^{2+} over Ca^{2+}), the equilibrium monomer concentration is $\sim 0.1 \mu\text{M}$ under polymerizing conditions. This monomer concentration, the 'critical concentration', is always found in solution at equilibrium

Figure 2 Assembly/disassembly of actin alone. Nucleation is highly unfavorable, signified by the large back arrows in the dimerization and trimerization steps. Once a tetramer is formed, the filament is more stable and monomers add to and disassemble from each end with the indicated kinetic constants (Pollard TD (1986) Rate constants for the reaction of ATP- and ADP-actin with the ends of actin filaments. *Journal of Cell Biology* 103: 2747–2754). Similar constants were determined more recently by a second method (Kuhn JR and Pollard TD (2005) Real-time measurements of actin filament polymerization by total internal reflection fluorescence microscopy *Biophysics Journal* 88: 1387–1402). Subunits hydrolyze bound ATP slowly upon addition to filaments, and release the Pi product even more slowly, creating sectors of the filament enriched in ATP-actin (yellow), ADP-Pi-actin (orange), and ADP-actin (red). Upon release from the filament, the ADP on the monomer exchanges slowly with ATP.

under these conditions. The concentration of actin in filaments is the excess above $0.1\ \mu\text{M}$. In other words, given $4\ \mu\text{M}$ actin under polymerizing conditions, $3.9\ \mu\text{M}$ will be in filaments and $0.1\ \mu\text{M}$ as monomers. With $100\ \mu\text{M}$ actin, $99.9\ \mu\text{M}$ is in filaments and, $0.1\ \mu\text{M}$ as monomers. At or below $0.1\ \mu\text{M}$, there are no filaments. Even at equilibrium, monomers constantly add to and release from both ends.

Polymerization Conditions

Three buffer conditions strongly affect actin's propensity to polymerize: ionic strength, the divalent cation present, and pH. Increased ionic strength increases elongation rate. The reason for this effect is not well understood but thought to be due to masking of charge repulsion between the highly anionic actin monomers. The ionic effect reaches a maximum at around the equivalent of $50\ \text{mM}$ KCl, and higher concentrations slow polymerization, probably due to inhibition of specific inter-monomer charge interactions in the filament. As for divalent cation, Mg-actin is better than Ca-actin at polymerizing, due to differences in monomer conformation. For pH, higher pH inhibits polymerization, likely due to increasing

the net negative charge of actin, hence increasing charge repulsion between monomers.

Effects of Actin-Binding Proteins

Actin-binding proteins are widely expressed in eukaryotes, generally at concentrations that exert a significant effect on cellular actin assembly/disassembly. Each protein alters one or more aspects of actin's assembly/disassembly cycle. The basic biochemical functions of these proteins are discussed in this section and illustrated in Figure 3, while their coordinated cellular effects are described in the next section.

Sequestering Proteins

Sequestering proteins, present in most eukaryotic cells, bind actin monomers and prevent their addition to either end of filaments (Figure 3). Metazoan cells often contain the small protein, thymosin ($5\ \text{kDa}$), the most well-characterized isoform being thymosin $\beta 4$. Yeasts do not have thymosins, but do express twinfilin, which can sequester. Twinfilin is present in mammals and other organisms as well.

Figure 3 Effects of actin-binding proteins on actin dynamics. (a) Sequestering proteins (green oval) bind actin monomers and prevent addition to either end of the filament. (b) Profilin (light blue circle) binds monomers and has three effects: (1) acceleration of nucleotide exchange on monomers; (2) prevention of monomer addition to pointed ends; and (3) inhibition of spontaneous nucleation. (c) Capping proteins (light blue oval) bind filament barbed ends and prevent monomer addition. (d) ADF/cofilin (gray trapezoid) binds ADP-subunits on filaments and promotes P_i release from other subunits. ADF/cofilin also severs filaments. These two activities result in accelerated filament depolymerization. Actin colors: yellow = ATP, orange = ADP- P_i , red = ADP.

Profilin

Profilin is a 13-kDa protein that binds actin monomers, preferring ATP-actin over ADP-actin about fivefold. Profilin binding has three consequences for actin (Figure 3). First, profilin strongly inhibits spontaneous nucleation. Second, profilin prevents monomer addition to pointed ends. Third, profilin serves as a nucleotide exchange factor for actin, increasing exchange of ATP or ADP at least fivefold, though by some accounts its effect is much greater. A common misconception is that profilin is a sequestering protein. The profilin-bound actin monomer can add to barbed ends at a rate comparable to that of free monomer. An additional feature of profilin is that it binds stretches of polyproline found in many cytoskeletal proteins (e.g., vasodilator-stimulated phosphoprotein (VASP), formins, WASp/Scar/WAVE family proteins, and vinculin), binding such proteins and an actin monomer simultaneously. In the case of formin proteins, which bind filament-barbed ends, profilin-actin binding can accelerate barbed-end elongation rate dramatically by increasing the efficiency of actin monomer addition to barbed ends.

Capping Proteins

Capping protein is a heterodimer of 30-kDa subunits that binds filament barbed ends, preventing monomer addition (Figure 3). With barbed ends capped, the critical concentration of actin shifts to 0.7 μM , the critical concentration of the pointed end. Capping protein's high affinity ($K_d < 1 \text{ nM}$) and slow off-rate (half-life of capped barbed end is 30 min) cause a stable block to barbed-end elongation. Members of the gelsolin family also cap barbed ends, in addition to severing filaments.

ADF/Cofilin

ADF/cofilin is a 15-kDa protein that binds both filaments and monomers, with a 40-fold preference for the ADP-bound state over ATP- or ADP-Pi states in both cases. Mammals contain two isoforms, ADF and cofilin. ADF/cofilin binding to filaments is cooperative and accelerates Pi release from other subunits on the filament at least 20-fold. ADF/cofilin also severs filaments. ADF/cofilin is often referred to as a depolymerization factor, because its binding to filaments accelerates depolymerization. The mechanism of depolymerization acceleration probably involves both acceleration of Pi release (increasing subunit off-rate from filaments) and severing (creating more ends for depolymerization). However, ADF/cofilin does not prevent polymerization, as ADF/cofilin-bound monomers can still add to filaments.

Cellular Aspects of Actin Assembly/Disassembly

In mammalian cells, actin concentration is in the 50–200 μM range. Since the critical concentration is 0.1 μM , one would expect the vast majority of actin to be in filaments. However, the ratio of polymerized:unpolymerized actin is often around 1:1 in unactivated cells, while activated cells can reach close to

100% polymerized actin. The 1:1 ratio is maintained largely by the proteins discussed. Many mammalian cells contain more thymosin than actin, as well as a high concentration of profilin (e.g., neutrophils have $\sim 200 \mu\text{M}$ actin, 400 μM thymosin, and 100 μM profilin). Despite its lower concentration, profilin binds ATP-actin more tightly than thymosin (K_d of 0.2 μM vs. $> 10 \mu\text{M}$), so that monomers distribute between the two proteins. The rapid off-rates of monomers from these proteins (at or above five per second) allow rapid equilibration. Almost all monomers are bound to one protein or the other, leaving $\sim 0.5 \mu\text{M}$ free actin monomer in cells. This low free monomer concentration virtually eliminates spontaneous nucleation in cytoplasm. Another consequence of these two proteins is that pointed-end elongation is effectively suppressed, since thymosin prevents elongation from both ends and profilin prevents pointed-end elongation. For this reason, cellular filaments only elongate from barbed ends (except under specific conditions in muscle cells).

Cellular actin filaments are assembled by specific nucleation factors. Examples of such factors are Arp2/3 complex and formins. Both nucleation factors are tightly regulated. Thus, cells control the when and where of filament formation.

Mammalian cells contain $\sim 1 \mu\text{M}$ capping protein, and its high affinity for barbed ends means that new filaments are capped rapidly ($\sim 1 \text{ s}$ after formation). Capping protein is inhibited by bound polyphosphoinositides, which can promote cellular filament elongation. Some proteins can also inhibit capping protein by competing for binding, specifically VASP and formins. By controlling capping, cells control filament elongation.

The mechanisms by which cellular filaments disassemble are not understood fully, since off-rates from pointed ends cannot explain the rapidity of disassembly in many circumstances. Filament networks hundreds of nanometers thick can disassemble in seconds. ADF/cofilin clearly has a central role in this process, probably both by catalyzing Pi release from filaments and by severing filaments to create new ends for depolymerization. There is, however, evidence that ADF/cofilin may contribute to filament assembly upon initiation of cell motility, perhaps by severing to create new ends capable of elongating and supporting Arp2/3 complex-based nucleation.

The coordinated action of these proteins results in a cycle of assembly/disassembly in cells (Figure 4). Monomers shift from thymosin to profilin, then add to the barbed end. The filament-bound monomer hydrolyzes its ATP and retains ADP and Pi. ADF/cofilin binding to the filament accelerates Pi release and causes filament severing. Monomers dissociate from the pointed end and remain bound to ADF/cofilin. Monomeric ADP-actin exchanges between ADF/cofilin, thymosin, and profilin. Even though ADF/cofilin binds more tightly than profilin to ADP-actin, profilin is at higher concentration (100 vs. $\sim 20 \mu\text{M}$), and the rapid off-rate from ADF/cofilin enables equilibration. Profilin catalyzes recharging of ATP onto its bound monomer, enabling re-addition of that monomer to the barbed end. Capping protein terminates barbed-end elongation except under specific circumstances.

The abilities of some proteins, such as formins and VASP, to bind at or near the barbed end have interesting consequences on actin dynamics. These proteins can compete with capping protein for barbed-end binding. In the absence of these

Figure 4 Concerted effects of actin-binding proteins in the assembly/disassembly cycle. Profilin-bound ATP-actin adds to the filament barbed end, then hydrolyzes its ATP slowly. ADF/cofilin binding accelerates Pi release along the filament and severs the filament. ADF/cofilin-bound ADP-subunits release from filament ends. Profilin, thymosin, and ADF/cofilin compete for binding ADP-monomers. Profilin-bound ADP-monomers exchange ADP for ATP, enhancing their ability to assemble onto barbed ends. Actin colors: yellow = ATP, orange = ADP-Pi, red = ADP.

proteins, capping protein terminates barbed-end elongation within seconds of filament nucleation, resulting in very short filaments. Barbed-end binding by formins or VASP, both of which generally allow barbed-end elongation, enables filaments to continue elongating. Capping protein inhibition is important for assembly of longer actin filaments, such as those in filopodia or microvilli.

The above description is probably accurate for most eukaryotes, including mammals, other vertebrates and multicellular animals, and protozoa. Fungi such as *Saccharomyces cerevisiae* (budding yeast) are somewhat different, containing lower actin and profilin concentrations (5–10 μM for each) and no thymosin. A yeast-sequestering protein, twinfilin, is present at unknown concentration. Unlike in vertebrates, most yeast actin (>90%) is polymerized. Yeasts contain ADF/cofilin, capping protein, Arp2/3 complex, and formins.

Actin assembly/disassembly in plants is poorly understood. Plants contain all the discussed proteins except thymosin. Plant profilin does not catalyze nucleotide exchange.

Other proteins, less well characterized at present, may play significant roles in actin assembly/disassembly. The Srv2/CAP complex may accelerate ADF/cofilin-mediated filament depolymerization and monomer recycling. Aip1 may associate with ADF/cofilin and cap barbed ends.

Reagents Used in Actin Research

Small Molecules Affecting Actin Dynamics

Table 2 presents a catalog of the reagents commonly used in actin research. While this table is simplistic, the effects of some reagents are not, and care must be taken to avoid artifacts. An example is the cytochalasins, a group of compounds commonly used to depolymerize cellular actin. This effect is attributed to the barbed-end-capping activity of cytochalasins. With barbed ends capped, filaments depolymerize from pointed ends since profilin and thymosin prohibit pointed-end elongation. However, at higher concentrations, cytochalasins can have other effects, such as causing ATP hydrolysis on actin monomers through nonproductive dimer formation. Use of

Table 2 Small molecule reagents used in actin research

Reagent	Biochemical effect	Cellular effect	Cell permeant?
Latrunculin A	Sequesters monomer	Depolymerization	Yes
Cytochalasins	Cap barbed ends	Depolymerization	Yes
Swinholide A	Sequesters dimers, severs filaments	Depolymerization	Yes
Phalloidin	Binds filaments	Prevent depolymerization	No
Jasplakinolide	Binds filaments	Prevent depolymerization	Yes

concentrations below 1 μM largely suppresses this secondary effect. In addition, cytochalasin B binds and inhibits a plasma membrane glucose transporter. Despite this property, cytochalasin B is sometimes used in preference to cytochalasin D, because the 10-fold lower affinity of cytochalasin B for barbed ends enables more rapid wash-out during cellular recovery experiments.

Latrunculins (isomers A and B) can cause a similar cellular effect to cytochalasins (depolymerizing filaments), but by a different mechanism (sequestering monomers). In neither case do these compounds actively depolymerize filaments. What they do is block polymerization, leaving only depolymerization to occur by the normal cellular mechanisms.

Swinholide A binds/severs filaments, and binds/sequesters dimers, again causing cellular actin depolymerization. This compound has not been widely used in actin cell biology.

Two compounds – phalloidin and jasplakinolide – stabilize filaments. Phalloidin is much better characterized. In the presence of phalloidin, the off-rate from barbed and pointed ends drops to near zero, and the critical concentration essentially becomes zero. Phalloidin also slows Pi release significantly. Phalloidin can be labeled with many compounds, including fluorophores, enabling localization of actin filaments in permeabilized cells. Isothiocyanate derivative of rhodamine

(TRITC) – phalloidin is especially useful, since its fluorescence increases 20-fold upon binding filaments. Since phalloidin is not cell permeable, jasplakinolide is used for live cell studies. For either compound, concentrations equal to those of actin are necessary to block depolymerization fully, because they bind stoichiometrically along the filament.

Glossary

Actin depolymerizing factor (ADF)/cofilin Related actin-binding proteins that increase the turnover of actin filaments *in vivo* through severing. The ADF-H domain is used to build larger versions of related proteins that can sever and cap filaments.

Arp2/3 complex A complex of two actin-related proteins, Arp2 and Arp3, with five other proteins that can nucleate the growth of new actin filaments and cause branching of filaments at the leading edge of a migrating cell.

Enabled/vasodilator-stimulated phosphoprotein (Ena/VASP) A family of actin-binding proteins that bind to but do not cap the growing barbed end of actin filaments, reducing branching and aiding in growth of long filaments.

F-actin The dynamic filamentous cytoskeletal structures, composed of subunits of actin monomer (G-actin), which organize the cytoplasm to maintain the shape of eukaryotic cells.

Filament capping The binding of a protein at the end of an actin filament to stop filament growth or depolymerization.

Filament severing The process whereby a protein binds along the side of an actin filament and severs the filament into two smaller pieces.

Filament treadmilling The dynamic process in which actin filaments elongate at their barbed (plus) end by addition of subunits and at the same time disassemble at their pointed (minus) end with loss of subunits.

Filopodia Finger-like protrusions with sensory capability that extend from the cell membrane and contain a bundle of parallel cross-linked actin filaments with uniform polarity.

Lamellipodia Flat web-shaped membrane protrusions containing highly branched actin filaments, seen at the leading edge of many migrating cells.

Wiscott–Aldrich syndrome protein (WASP) A family of proteins involved in activation of the Arp2/3 complex and actin-filament nucleation.

Overview

Actin is one of the major components of the cytoskeleton, a network of protein filaments that organizes the cytoplasm of eukaryotic cells. Actin filaments (F-actin), in the form of a right-handed double-stranded helix, are formed by assembly of globular (G-actin) monomer subunits in a head-to-tail orientation that gives the filaments a molecular polarity. Based on the orientation of an arrowhead pattern on F-actin decorated with a fragment of the muscle motor protein myosin, one end of the filament is called the barbed end and the other the pointed end. Spatial and temporal regulation of actin-filament assembly, disassembly, and stability in cells drives most aspects of cell motility, cell shape, and the interaction of a cell with its neighbors or surrounding matrix. These multifaceted cellular functions of actin are tightly regulated by more than 100 actin-binding proteins (ABPs) that interact with either G-actin or F-actin. Actin-capping and -severing proteins are special classes of ABP that regulate the assembly dynamics of actin filaments. Actin-capping proteins are classified into two groups, the barbed-end-capping proteins and the pointed-end-capping proteins. Depending on their binding affinity and off-rate constants, capping proteins slow down or stop the growth and/or depolymerization of filaments at the end to which they bind. Their interaction with actin may promote nucleation of new filaments, increase branching of filaments, and/or enhance filament depolymerization. Actin-severing proteins bind to the side of actin filaments and enhance fragmentation. Some severing proteins also become barbed-end-capping proteins (e.g., gelsolin), whereas others (e.g., actin depolymerizing

factor (ADF)/cofilin) can provide both free barbed and pointed ends that can influence actin dynamics.

Actin

Actin is a major cytoskeletal protein virtually in all eukaryotic cells, often comprising 2–5% of total cellular protein (total cellular concentration 50–200 μM). In muscle cells where it was first identified, F-actin is the major component of the thin filaments of the contractile apparatus where the myosin motor head groups of the thick filament walk along the actin thin filaments in an energy-dependent process, causing contraction. Mammals have six actin genes, each expressing a different isoform, but the structure of the 42.5-kDa actin monomer is highly conserved across phyla. G-actin has four quasi-subdomains, at the center of which is bound an essential adenine nucleotide, either adenosine triphosphate (ATP) or adenosine diphosphate (ADP). As is the case with most molecular self-assembly systems, actin assembly is driven by a positive entropy change that arises from the displacement of water as the subunits come together. Following assembly, bound ATP is rapidly hydrolyzed to ADP and inorganic phosphate (P_i), whose dissociation to yield ADP-actin is about 100 times slower than hydrolysis. Nucleotide hydrolysis provides the energy input required for actin filaments to maintain equilibrium-binding constants for monomers that differ at the barbed and pointed ends. The concentration of monomer required to maintain the filament end is called the critical concentration, and is lower for the barbed end than for the pointed end. Thus, as monomer

Figure 1 (a) Slow nucleation of actin-filament formation *in vitro* results from the instability of actin dimers and trimers. Spontaneous nucleation of actin from monomer does not occur *in vivo* due to sequestering of monomer. When actin monomer is plentiful, filaments can elongate from both ends, but grow faster from the barbed end. (b) Dynamics of actin filaments at steady state demonstrating treadmilling. ATP-actin adds onto the barbed end, nucleotide hydrolysis occurs rapidly, and the inorganic phosphate dissociates slowly leaving ADP-actin subunits to dissociate from the pointed end. Nucleotide exchange of ATP for ADP occurs on the monomer, giving rise to more ATP-actin for filament growth.

assembles into filaments, the monomer concentration decreases and the critical concentration of the pointed end is reached first. Monomers still add to the barbed end, leading to monomer loss from the pointed end. This phenomenon is called 'treadmilling'. At steady state, there is consumption of energy through ATP hydrolysis that drives the treadmilling of the actin subunits (Figure 1). In some cells this may account for up to 50% of the total ATP consumption. Tropomyosin (Tm), a short helical filamentous ABP, binds along the side of actin filaments and covers five to seven actin subunits. Binding of Tm usually aids in the formation of stable actin filaments, in part because some Tms can inhibit the severing and depolymerizing activity of other ABPs. However, there are more than 40 different isoforms of Tms formed by alternative splicing of the four Tm genes, and some of these might enhance actin dynamics by maintaining filaments in a conformation that enhances the binding of severing proteins. Dimers of actin are not stable and tend to dissociate, but, with the addition of another monomer, the trimeric actin acts as a nucleus for filament formation (Figure 1). In the cell, spontaneous nucleation of filaments is kept at minimum by the presence of actin monomer sequestering proteins. Thus, nucleation is a highly regulated event and may be initiated in the cell by three mechanisms: (1) the activation of certain actin-binding proteins that help form trimeric nuclei; (2) the removal of capping proteins from the filament barbed ends; and (3) the severing of existing filaments to provide new barbed ends for filament elongation. The sites of nucleation and directionality of actin-filament growth are important for the development of cell polarity and cell migration and are regulated, in part, by the localized activity of capping and severing proteins.

Actin Dynamics at the Leading Edge

Various cell membrane protrusions and inversions, especially lamellipodia, filopodia (microspikes), phagocytic cups, and upward ruffles, are distinct morphologies of cells and are important for cell function, motility, and organismal development. These leading-edge phenomena are based on actin-filament reorganization. In extending lamellipodia and filopodia, polarized arrays of actin filaments turn over very rapidly, with filament barbed ends facing toward the plasma membrane. The pointed ends of the filaments rapidly depolymerize at the rear of these arrays. In extending lamellipodia, the actin-filament growth is regulated mainly by formin, enabled/vasodilator-stimulated phosphoprotein (Ena/VASP), capping protein, Arp2/3 complex, and actin-filament cross-linking proteins. The Arp2/3 complex causes branching of growing actin filaments, and the barbed-end-capping protein limits the growth of newly assembled filaments to maintain short, rigid filaments that can serve to push the membrane forward in the broad lamellipodium. Ena/VASP proteins and formins bind to the barbed ends of growing actin filaments and inhibit the binding of capping protein and the Arp2/3 complex, leading to the formation of longer and unbranched actin filaments, such as those found in the finger-like filopodial extensions (microspikes). This antagonism in barbed-end binding between formins and Ena/VASP on the one hand, or Arp2/3 complex and capping protein on the other, can help explain the often rapid conversion between lamellipodial and filopodial membrane protrusions seen at the leading edge of many migrating cells, especially the growing tip of neurons, called the growth cone (Figure 2). The remodeling of

Figure 2 (a) A typical dorsal root ganglion neuronal growth cone. Phase-contrast picture on left shows growth cone exhibiting lamellipodial growth. (b) Within a few minutes after reducing the osmolarity of the growth medium, the growth cone exhibits many long and active filopodia. Panel width = 44 μm . (c) Schematic of a migrating cell showing filopodia with straight long actin-filament bundles, lamellipodia with a branched actin network, and the cell body with long actin-filament bundles linked to sites of adhesion. The bundles are referred to as stress fibers in nonmotile cells but as graded polarity actin bundles in highly migratory cells because of the changes in orientation of the filaments within the bundles in going from the front to the rear of the cell.

the actin cytoskeleton for this conversion also requires actin-severing proteins, such as ADF/cofilin.

Pointed-End Binding and Branching

Arp2 and Arp3 are two actin-related proteins that form part of a seven-subunit complex known as the Arp2/3 complex, ubiquitous in eukaryotes. The Arp2/3 complex is required for generating the 70° branched actin filaments observed at the leading edge of expanding cell membranes in lamellipodia. There are at least two mechanisms for generating this type of filament array. The Arp2/3 complex may capture the pointed ends of actin filaments created by severing pre-existing filaments and then associate with the side of another pre-existing filament to create a branch point. Alternatively, Arp2/3 complex may bind at the side of a growing filament to create a branch point. The Arp2/3 complex requires activation to become a potent nucleator of actin-filament growth. Activation can occur through the binding of members of the Wiskott-Aldrich syndrome protein (WASP) family, some of which are activated by signaling through G-protein-coupled receptors and others by Cdc42, a Rho family GTPase. The Arp2/3 complex can also be activated by other mechanisms. The active Arp2/3 complex can bind an actin monomer and initiate the nucleation of a new filament at an angle of ~70° to the mother filament. This branched actin-filament network, called the dendritic brush, generates the force required for cell protrusion at the leading edge (Figure 3).

To maintain proper stiffness and the best angle for membrane expansion, the filaments are not allowed to grow very long before their barbed ends are capped by capping protein. The branching of filaments is inhibited by the binding of at least some forms of Tm, which prevent Arp2/3 binding, and branching is also inhibited by proteins in the Ena/VASP family.

Evolutionary and Structural Relationships between Some Severing and Barbed-End-Capping Proteins

The present sequence, structural, and biochemical data suggest that many of the actin-binding proteins have evolved through gene duplication or mutation of DNA sequences encoding a small number of protein motifs. For example, proteins in the ubiquitous eukaryotic ADF/cofilin family are derived from a single 15-kDa module (the ADF-H domain), can interact with both G- and F-actin, and have F-actin-severing activity but do not cap filaments. Proteins containing one, two, three, and six copies of the ADF-H domain have evolved for regulating actin dynamics and will be discussed separately later. Although ADF/cofilins and some of the ADF-H domains within the six-ADF-H-domain family members show little or no sequence homology, structurally they display similarity on overall folding and secondary/tertiary structural elements, suggesting that both divergent and convergent evolutionary mechanisms have given rise to these structurally related molecules. Another common actin-binding motif is found in proteins containing the

Figure 3 Schematic of actin-filament dynamics at the leading edge of a cell. (1) Activation of the Arp2/3 complex by WASP can cause *de novo* nucleation of filaments, but active Arp2/3 complex may also be captured by pointed ends of existing filaments (3). (2–4) Arp2/3 complex nucleates from the side of actin filaments or, when bound to pointed end of actin filament, is captured along the side of a filament to create the 70° branches. Further growth of barbed ends with rapid capping and nucleation of new branches leads to complex networks of actin filaments (4). (5) ADF/cofilin-mediated severing and depolymerization of the filament arrays occurs when subunits become ADP-actin. Release of ADF/cofilin (6) and enhanced nucleotide exchange by profilin and Srv2/CAP (7) provide profilin-actin complex that serves as a monomer pool for filament growth (8), especially during formin-mediated elongation (10). Leimodin (also cordonbleu and others) nucleate actin filaments, allowing growth at the barbed end. They remain associated with the pointed as a pointed-end-capping protein (9), whereas formin nucleates and moves with the growing barbed end to form straight actin filaments (10).

WASP homology domain 2 (WH2), which evolved as a versatile, short (17–27 amino acid), flexible α -helical motif that can bind actin by a hydrophobic interaction. Proteins with this motif have many diverse functions with regard to actin, including nucleation, capping, severing, and monomer sequestering activity.

Proteins with ADF-H Domains

The Single-Domain ADF/Cofilin Family

Cell motility and morphogenesis require high rates of actin-filament turnover, ~100–150-fold faster than occurs for purified actin *in vitro*. The ADF/cofilins are 13–19-kDa proteins containing a single ADF-H domain that are required for this high rate of actin-filament dynamics. They have been isolated or identified by genomic or complementary DNA (cDNA) analysis from more than 40 different animals, higher plants, fungi, yeasts, and protists. The lethality of the loss of the ADF/cofilin gene in organisms that express only a single gene for this family (e.g., yeast) demonstrates the essential nature of these proteins. Mammals have three separate genes for these proteins: the ubiquitous cofilin 1, ADF, and cofilin-2, which are found mostly in skeletal muscle and also in low amounts in other

tissues. Within any given mammal, the three proteins are ~70% identical. In an ADF-null mouse, cofilin 1 expression is up-regulated to compensate for the loss of ADF and the animals are viable. The only major defect observed is that the mice become blind due to corneal thickening, even though cofilin 1 is up-regulated in the cornea. This finding, along with differences in the quantitative behavior of the three proteins *in vitro*, suggests that each isoform has some unique tissue-specific functions. Many ADF/cofilins have nuclear localization sequences, but the protein is usually cytosolic. However, it can be targeted to the nucleus, along with cytoplasmic actin, under certain conditions. Its nuclear transport may simply be a mechanism for uptake of actin, which has many nuclear functions in chromatin remodeling and transcription. However, in plants, nuclear ADF has a transcriptional role.

ADF/cofilins enhance filament turnover (dynamize filaments) by severing filaments in a concentration-dependent manner. At low ratios with F-actin subunits, cofilin has been shown to continuously sever filaments. At higher ratios, cofilin binds cooperatively along the filament, stabilizing a twisted form of the F-actin, which leads to rapid severing and also stabilization of the shorter cofilin-saturated pieces of F-actin. If there is a low concentration of available actin monomer, severing of F-actin provides more pointed ends from which

Figure 4 Diagrams showing actin-filament capping and severing by different types of molecules. ADF/cofilin: (1) binds cooperatively and with highest affinity to ADP-actin subunits and (2) severs actin filaments. (5) Stable filaments are generated by tropomodulin binding to pointed ends, CapZ binding to barbed ends, and tropomyosin binding along filament length. ADF/cofilin competes for F-actin binding with some tropomyosins (6). Cooperative activity between ADF/cofilin and Aip1 can lead to faster severing of tropomyosin-decorated filament. Coronin also aids ADF/cofilin to sever ADP-actin filaments (7). (4, 7) PIP₂ regulates the binding of many capping proteins, dissociating both gelsolin and CapZ from barbed ends of actin filaments. (2, 3) Actin-filament capping and severing by gelsolin.

dissociation of subunits can occur leading to more rapid filament depolymerization. If the environment contains assembly-competent actin, the severed filaments can promote filament nucleation and elongation. ADF/cofilins bind ADP-actin subunits or monomer with higher affinity than they bind to ATP-actin. Thus, within an actin filament, ADF/cofilin binding is preferentially toward the pointed end, the desired region for filament turnover in cells (Figures 3 and 4). However, cofilin has a stronger nucleating activity than ADF, resulting in ADF having stronger monomer sequestering activity *in vivo*. If F-actin is severed by ADF/cofilin at the leading edge of cells where active Arp2/3 complex is present, the Arp2/3 complex can capture the pointed ends of the newly severed filaments and bind them along the side of existing filaments to create the highly branched network found in lamellipodia.

ADF/cofilin activity is regulated by pH-dependent phosphatidylinositol 4,5-bisphosphate (PIP₂) binding as well as by pH effects on the ADF/cofilin-actin filaments resulting in greater depolymerization at pH > 7.3, whereas pH < 7.1 favors F-actin binding. ADF/cofilin-mediated F-actin severing is inhibited by some of the larger isoforms of tropomyosin (e.g., TM5_{NM1}), which can stabilize F-actin in a conformation that is not conducive to ADF/cofilin binding. However, there may be one or more isoforms of tropomyosin (e.g., TMBr3) that can enhance the dynamizing activity of ADF/cofilin. Actin binding, and thus ADF/cofilin activity, is inhibited by phosphorylation at a highly conserved serine residue (the encoded Ser 3 in mammalian ADF and cofilin, which is Ser 2 in the demethionated and N-acetylated processed proteins). Two related kinases, the LIM (LIM domain first discovered in proteins Lin11, Isl-1 & Mec-3) kinases and TES (named for testes in which they were first discovered) kinases, each with two members, phosphorylate ADF/cofilins at

this site. The regulated removal of the phosphate from Ser3 (activation) is accomplished by specific phosphatases in the slingshot or chronophin families, although more general phosphatases may sometimes play a role. Both the kinase and phosphatase pathways are regulated by upstream signaling events through which extracellular signals affect actin dynamics. Although phospho-cofilin is inactive in binding either G- or F-actin, it is an activator of phospholipase D1, an important protein in generating membrane phosphatidic acid, a requirement in some cells for the establishment of polarized migration through interaction with the dedicator of cytokinesis (DOCK) family of proteins, which are guanine nucleotide exchange factors for generating the active form of the small GTPase Rac1. Because Rac1 is an activator of the p21 kinase (Pak), which activates LIM kinase to phosphorylate cofilin, cofilin is both an upstream activator and a downstream effector of Rac1 signaling.

Mammalian cofilin has four free sulfhydryl groups. The actin-binding activity of cofilin is altered by the oxidation of these cysteine residues to form either one or two internal disulfides. Cofilin with a single internal disulfide formed between Cys39 and Cys80 is still able to bind F-actin but does not enhance dynamics of the actin, whereas cofilin with two disulfides (Cys39–Cys80 and Cys139–Cys147) does not bind to actin but rather is targeted to mitochondria where it promotes mitochondrial-dependent apoptosis through cytochrome *c* release.

The Two-ADF-H-Domain Twinfilin Family

Twinfilin (Twf), a 40-kDa protein with two ADF-H domains connected by a small linker region, is a multifunctional actin-binding protein, also found across the phyla. Mammals have

two Twf isoforms, whereas only one isoform occurs from yeast to flies. Twf binds tightly with ADP actin and this activity is regulated by PIP₂. Yeast Twf at neutral pH sequesters actin monomer to prevent spontaneous actin-filament assembly, but under more acidic conditions (pH < 6.0) it can also sever actin filaments. In budding yeast, Twf binds to capping protein, which is necessary for Twf to localize to the cortical actin cytoskeleton. Mouse Twf1 caps filament barbed ends, but with highest affinity only to those made up of ADP actin, such as one finds on severed filaments.

The Three-ADF-H-Domain Proteins: CapG, Severin, and Fragmin

CapG, severin, and fragmin are gelsolin family proteins containing three ADF-H segments that have Ca²⁺-dependent barbed-end-capping and -severing activity. The first segment (S1) binds to G-actin and has the capping function, whereas segments 2 and 3 (S2, S3) bind to F-actin. CapG is a 39-kDa barbed-end-capping protein, the name reflecting its capping function and structural similarity to gelsolin, though only half of its size. CapG is highly expressed in macrophages and was initially known as macrophage capping protein, gCap39 or Mbh1. CapG has a structure similar to severin and fragmin, but it does not sever actin filaments as do severin and fragmin. CapG caps barbed ends of actin filaments at micromolar concentrations of Ca²⁺, but it dissociates from barbed ends when Ca²⁺ levels return to their normal nanomolar levels, whereas gelsolin remains bound to the barbed ends under the same conditions. CapG is important for the actin-based motility of macrophages. PIP₂ binds to CapG, thereby inhibiting its binding to F-actin. The actin monomer sequestering protein profilin is also able to dissociate CapG from actin-filament barbed ends when profilin is present at high concentration (>10 μM).

CapG is also found within the nucleus as well as the cytoplasm, but its nuclear function is unknown. Although CapG lacks a nuclear export signal, which is present in severin and fragmin, CapG does not contain any known nuclear localization signal. Thus, the method by which it is translocated into the nucleus is also unknown. CapG is also found associated with the mother centriole in interphase cells, with the mitotic spindle during mitosis, and in the midbody ring during abscission. Localization to these structures suggests that CapG may work as a mediator between the actin cytoskeleton and microtubules, and may have a greater role in motile processes than previously appreciated. Severin and fragmin, found in the slime molds *Dictyostelium* and *Physarum*, respectively, are structurally similar to CapG, but they also bind to the side of and sever F-actin as well as cap the barbed ends of the severed filaments. They have two Ca²⁺-binding sites and can be thought of as small versions of the six-ADF-H-domain protein, gelsolin.

The Six-ADF-H-Domain Proteins: Gelsolin, Villin, and Adseverin/Scinderin

Gelsolin, villin, and adseverin/scinderin contain six ADF-H repeats and presumably arose through duplication of the gene for the ADF-H three domain proteins. These proteins, often referred to as the gelsolin family, also have F-actin barbed-end-capping and -severing activity. The N-terminal

half of these proteins, with three repeats similar to CapG, severin, and fragmin, is able to bind two actin monomers and sever actin filaments. The C-terminal half is able to bind to a single actin monomer at elevated Ca²⁺ concentration.

Gelsolin, with a mass of 80 kDa, is expressed in all eukaryotes. The name arose from its ability to rapidly dissolve an actin gel and convert it into a soluble form. The N-terminal half of gelsolin contains two Ca²⁺-binding sites, one of which is high affinity, in the submicromolar range. Gelsolin severs actin filaments at Ca²⁺ concentrations >10⁻⁵ M. The severing mechanism probably involves the binding of gelsolin along the side of the filament and intercalation between actin subunits during the normal thermal-induced flexing of the actin. After severing filaments, gelsolin remains bound to the barbed end of one new filament (Figure 4) and produces a new pointed end. At Ca²⁺ concentrations in the submicromolar range, gelsolin acts to cap barbed ends of actin filaments. An extracellular (secreted) isoform of gelsolin with molecular mass 83 kDa, called serum gelsolin, circulates in blood where it severs and caps actin filaments released from lysed cells. The resulting monomers of actin are then sequestered by vitamin D-binding protein, also a potent actin monomer-binding protein, and ultimately removed from circulation by liver. This mechanism prevents accumulation of actin filaments in the blood, which could potentially block circulation in capillaries.

Gelsolin binding to F-actin is inhibited by tropomyosin in two ways. Tropomyosin binding to F-actin induces a cooperative conformational change in actin filaments resulting in dissociation of gelsolin. Second, tropomyosin can directly bind gelsolin and thereby dissociate gelsolin from actin-gelsolin complex. Dissociation of gelsolin by tropomyosin from a gelsolin-capped actin filament leads to the formation of long filaments from smaller gelsolin-actin complexes, even from gelsolin-actin heterodimers, heterotrimers, and heterotetramers. PIP₂ can bind directly to gelsolin and dissociate gelsolin that is bound to the barbed end of an actin filament, yielding a free barbed end for growth. Gelsolin can be proteolytically cleaved by caspase-3 during apoptosis. The short amino-terminal (residues 1–352) cleavage fragment does not need Ca²⁺ for severing existing actin filaments and contributes to the progression of apoptosis.

Villin, a gelsolin family member with molecular mass of 92.5 kDa, controls actin assembly in the microvilli of epithelial cells. Villin has the unique property of being able to bundle actin filaments through an 8-kDa F-actin-binding module known as the villin headpiece. The activity of villin is highly regulated by Ca²⁺. At submicromolar Ca²⁺ concentrations, villin bundles actin filaments, whereas at micromolar Ca²⁺ concentrations it caps barbed ends of actin filaments and at >100 μM Ca²⁺ it severs F-actin. As with gelsolin, the activity of villin is regulated by both PIP₂ and Ca²⁺. In addition, villin is also regulated by phosphorylation on tyrosine residues in intestinal epithelial cells, a requirement for regulating the interaction of actin filaments with apical ion channels. Deletion of the villin gene in mice leads to accumulation of actin filaments within the epithelial cells making them prone to injury.

Adseverin, also known as Scinderin, is only expressed in secretory cells. It has slightly different temperature and Ca²⁺ sensitivity from gelsolin, but its functions appear to be very similar. During cell stimulation by Ca²⁺, adseverin is activated and disassembles cortical F-actin to allow secretory vesicle

exocytosis. As with gelsolin, adseverin binds to and is regulated by PIP₂.

Other Severing, Severing-Enhancing, or Dynamizing Proteins

Molecules Interacting with CasL

Molecules interacting with CasL (Micals) are multidomain cytosolic proteins found in both vertebrates and invertebrates that bind to the semaphorin 1a receptor, plexin A. Three vertebrate genes encoding Micals have been identified. Micals have a calponin homology (CH) domain in their N-terminal half that is involved in actin-filament binding, a polyproline-rich region that binds the SH3 domain of the focal adhesion docking protein CasL, and a C-terminal ezrin/radixin/moesin (ERM) domain needed for linking F-actin to plexin A. However, of particular interest is the N-terminal enzymatic flavoprotein monooxygenase domain that provides a redox-regulated depolymerization of actin filaments that will even depolymerize fascin-bundled F-actin in a reduced nicotinamide adenine dinucleotide phosphate (NADPH)-dependent manner. Micals regulate *Drosophila* bristle and neuronal growth cone morphology and mediate semaphorin-induced changes in cell shape. Micals are unique actin-severing proteins in that they are regulated directly through redox signaling.

Actin-Interacting Protein 1

Actin-interacting protein 1 (Aip1), an actin-filament-capping protein with a mass of ~65 kDa, has 8–14 repeats of a structural motif, often terminating in a tryptophan (W)-aspartic acid (D) dipeptide, called a WD domain. Each WD domain forms a four-stranded antiparallel β -sheet (or blade), six or seven of which comprise a β -propeller, a structure found in many different proteins with diverse functions. Aip1, a ubiquitous eukaryotic protein, binds to F-actin weakly or not at all in the absence of ADF/cofilin, but caps the barbed ends of filaments severed and saturated by ADF/cofilin. Aip1 inhibits annealing of the ADF/cofilin-severed filaments, maintaining a higher filament number, and blocks the growth of the filament at barbed ends. It also enhances a more complete depolymerization of ADF/cofilin-bound filaments to generate actin monomers. Importantly, coordinate activity of Aip1 and ADF/cofilin can sever tropomyosin-decorated actin filaments. In the nematode *Caenorhabditis elegans*, which expresses two forms of ADF/cofilin, the ubiquitous unc60A and the muscle-specific unc60B, only the weaker F-actin-binding/severing unc60B is able to form a high-affinity complex with Aip-1 (unc78). Thus, Aip1 enhances the apparent severing activity of the weaker ADF/cofilins and gives this family of proteins the ability to function much like the severing and capping proteins discussed earlier.

Coronins

Coronins (Crns), WD repeat-containing actin-binding proteins widely expressed in eukaryotes, are localized to the leading edge of migrating cells, a region of highly dynamic actin.

Crns are involved in cell motility, phagocytosis, cytokinesis, and endocytosis. Lower eukaryotes express only a single isoform of Crns, whereas higher eukaryotes express multiple isoforms (up to 12 in vertebrates). All Crns have WD repeat domains at their N-terminal region, forming a β -propeller structure that is involved in both F-actin binding and, for a few isoforms (Crn1 and Crn3), membrane binding. Crns have a variable middle region and a C-terminal domain with a coiled-coil structure important for oligomerization and F-actin binding. Crn1 can regulate (inhibit) the activity of the Arp2/3 complex by direct binding, the only known direct inhibitor of Arp2/3 complex *in vitro*. *In vivo*, deletion of Crn isoforms 1, 4, and 11 leads to decreased filament turnover. In budding yeast, Crn induces actin-filament depolymerization at a high rate, working in collaboration with ADF/cofilin and Aip1. Crn further blocks the weak cofilin activity on newly synthesized ATP-actin filaments, but synergizes with cofilin and Aip1 for disassembly of older filaments composed primarily of ADP-actin (Figure 4).

Formins

Formins are actin-filament nucleators that bind to the barbed end of actin filaments. All formins have signature domains called the formin homology domains 1 and 2 (FH1 and FH2), the latter of which dimerizes and nucleates actin filament (Figure 3). There are more than 15 different formins present in humans with diverse and versatile functions. Some formins, such as the diaphanous-related formins, mDia1 and mDia2, are autoinhibited through intramolecular interactions involving an N-terminal diaphanous inhibitory domain (DID) interacting with a C-terminal diaphanous autoinhibitory domain (DAD, which has sequence similarity to the WH2 domain). These proteins are usually activated by the binding of Rho GTPase at an N-terminal Rho-binding domain, releasing the autoinhibition. The diaphanous-related formins, including mDia1-3, Daam1-2, and Bni1, do not sever filaments but rather help elongate filaments by recruitment of profilin-actin complexes to the growing barbed ends. However, the formin-like inverted formin 2 (IFN2) and FRL1 have both actin-severing and -nucleating activities. INF2 and FRL1 have a putative DAD domain with WH2 similarity, which plays a critical role in filament disassembly.

Cyclase-Associated Protein

Although its abbreviation might suggest an actin-capping function, cyclase-associated protein (CAP; aka Srv2) actually does not interact with F-actin. It was named for its association with adenylyl cyclase and is found in all eukaryotes. Its major function is in recycling actin subunits from ADF/cofilin-depolymerized actin. When ADF/cofilin depolymerizes actin, the binding of ADF/cofilin to ADP-actin inhibits the nucleotide exchange. CAP forms a multimeric protein complex with ADF/cofilin, actin, and profilin to exchange ATP for ADP on actin and recycle ATP-actin. The C-terminal half has a WH2 domain and binds monomeric actin. It also has two proline-rich regions through which it binds profilin. The N-terminal half also has one monomer actin-binding site.

Capping Proteins

In general, capping proteins bind weakly to actin monomer but often bind strongly to dimer and higher oligomers (F-actin). Thus, pointed-end-capping proteins can stabilize the dimer and enhance nucleation of filament growth. They have high affinity for the filament ends to which they bind and they usually bind in a 1:1 stoichiometry with the filament (Figures 3 and 4). The main function of capping is to restrict polymerization and depolymerization, thereby controlling filament length. As mentioned earlier, limiting the growth of actin filaments at the leading edge of migrating cells is important for actin-assembly-driven membrane protrusion (lamellipodial growth). Pointed-end-capping proteins are important for filament nucleation, branching, regulating filament turnover, and cross-linking of actin filaments to other components of the cytoskeleton.

Barbed-End-Capping Proteins

CapZ

The most abundant barbed-end-capping protein is CapZ (Figures 3 and 4). In striated muscle cells, CapZ binds to actin filaments at the Z-disk, where CapZ also interacts with α -actinin, an actin cross-linking protein, to anchor the thin filaments from the neighboring sarcomere, the contractile unit of skeletal muscle. Nonsarcomeric isoforms of CapZ are localized to sites of membrane-actin contact. CapZ is a heterodimer composed of α - and β -subunits, 32 and 31 kDa, respectively. Each subunit has two isoforms. Both subunits are structurally similar, though they lack sequence similarity, but assemble tightly to form a dimer with pseudo-twofold rotational symmetry. The C-terminal ends of each subunit are flexible, amphipathic α -helices necessary for actin binding. This flexibility explains how CapZ can tightly bind two actin subunits, or the barbed end of a double-stranded actin filament, with subnanomolar affinity. Cells have CapZ in a near 1:1 molar ratio with actin filaments and 1:100 to 1:150 with respect to total actin subunits. *In vivo*, PIP₂ binds CapZ directly to inhibit its capping activity. The generation of PIP₂ in platelets in response to thrombin uncaps actin-filament barbed ends, allowing localized filament growth needed for the shape changes of platelets associated with blood clot retraction. V-1/myotrophin, CKIP1, CD2AP, CARMIL, and myosin1-linker bind directly to CapZ to inhibit its capping activity. VASP, a member of the Ena/VASP family of proteins, also functions as an antagonist for CapZ as well as for other barbed-end cappers, such as gelsolin. Formin proteins have high affinity for barbed ends of actin filaments and also act as competitors for CapZ binding, enabling filament growth.

Tensin

Tensin, a large multidomain focal adhesion molecule with a mass of ~200 kDa, interacts with actin and several signaling molecules through Src homology 2 (SH2) and phosphotyrosine-binding (PTB) domains. Tensin caps the barbed ends of actin filaments within the focal adhesions of fibroblasts and muscle, and links the actin cytoskeleton to the focal adhesion through multiple interactions with other

adhesion molecules. Tensin is very susceptible to proteolysis, especially by the calcium-activated calpain-II. Full-length recombinant tensin shows complete capping activity, whereas insertin, most likely a proteolytic fragment of tensin, only partially caps F-actin.

Pointed-End-Capping Proteins

Tropomodulin

Tropomodulin (Tmod) is a unique pointed-end-capping protein first discovered as an actin-tropomyosin-binding protein (Figure 4). The name tropomodulin was given because it binds actin filaments tightly in the presence of tropomyosin. Human skeletal muscle Tmod has a mass of about 40 kDa. Four isoforms of Tmod have been identified, one of which is found mainly in erythrocytes (Tmod1), one in brain (Tmod2), one in skeletal muscle (Tmod4), and one (Tmod 3) which is widely distributed. Tmod caps the pointed end of actin filaments and in skeletal muscle plays an important role in the assembly of the sarcomere where it is present in a 1:1 molar ratio with respect to the thin filaments. The N-terminal half of Tmod is rod shaped and binds to the N-terminal part of the two tropomyosins that lie along the opposite sides of actin in thin filaments. The C-terminal half of Tmod is responsible for capping the pointed end of F-actin. Although Tmods 1 and 4 bind to actin filaments tightly, they do not bind to actin monomer. However, Tmod 3 is able to sequester actin monomers. At low concentrations, Tmod3 increases actin polymerization by nucleating filaments, but at high concentrations it decreases actin-filament polymerization, both by capping the pointed end and by sequestering monomer. Binding affinity of all Tmods to the pointed end of F-actin is significantly higher in the presence of muscle tropomyosin. Tmods from nonmuscle cells bind with differing affinities to F-actin containing different isoforms of tropomyosin, suggesting that it might play a role in sorting Tm isoforms to different filament populations and in modulating filament turnover through regulating the dynamics at filament pointed ends.

Leimodin

A 64-kDa protein, named leimodin (Lmod), has three isoforms. Lmods 1 and 3 are found in smooth muscle, and Lmod 2 is found in cardiac and skeletal muscle. Like Tmod, Lmod also caps filament pointed ends and acts as a potent nucleator of actin-filament formation (Figure 3). Lmod and Tmod have a similar N-terminal actin-binding domain and a similar leucine-rich region containing another actin-binding domain. However, Lmod has only a single tropomyosin-binding site in the N-terminal region, whereas Tmod has two, and Lmod has an extended C-terminus with a polyproline region and an actin-binding WH2 domain that are not present in Tmod. The three actin-binding domains of Lmod are able to form stable trimeric actin nuclei and allow filament elongation at the barbed end while Lmod remains bound at the pointed end. Lmod recruits muscle tropomyosin to stabilize the filaments that become part of the sarcomere. Indeed, the recruitment of different tropomyosin isoforms to specific families of actin filaments may depend, in part, upon the nature of the filament nucleation complex.

Spectrin/band 4.1

Spectrin/band 4.1 acts as an F-actin pointed-end-capping complex. These proteins are expressed in a wide variety of tissues in multiple isoforms. Spectrin/band 4.1-actin complex was first isolated from red blood cell (erythrocyte) membranes, where actin filaments are short and of uniform length. Both ends of these filaments are capped, the pointed end with spectrin/band 4.1, but the nature of the barbed-end-capping protein is not known. Spectrin, a member of a large calponin homology repeat family of proteins, binds to some transmembrane proteins and/or their cytoplasmic-associated linkers (e.g., ankyrin) as well as to actin, forming a cortical cytoskeleton in erythrocytes that can restore cell shape after distortion by passage through small capillaries. Band 4.1 belongs to a superfamily of proteins having a FERM domain (FERM, four point one, ezrin, radixin, and moesin) and bind to several other proteins.

Other Nucleating/Capping Proteins

As mentioned earlier, proteins containing the WH2 domain have many diverse functions with regard to actin. Except for cofilin, Tmod, and formins, other well-characterized nucleators of actin assembly, including Lmod discussed above, use the WH2 domain for interaction with actin. These WH2-containing proteins include Spire, Cordonbleu (Cobl), VopL/VopF, and TARP. A common architecture found in Spire, Cobl, and VopL/VopF consists of tandem WH2 motifs that bind multiple actin subunits, either in a longitudinal array

representing one strand of an actin filament that can dimerize to form a nucleation complex (Spire) or in a trimeric complex with subunits representing both actin protofilaments (Cobl). These complexes remain associated with the pointed ends of growing filaments.

Glossary

Actin-associated proteins Proteins that bind monomeric actin, actin filaments, or both, thereby altering respective actin properties. They are also known as actin-binding proteins (ABPs).

Barbed end/pointed end Opposite ends of intrinsically polar actin filaments with the barbed end (plus end) exhibiting more rapid dynamics than the pointed end (minus end).

Filopodia Thin, finger-like protrusions extending from the cell surface and responsible for probing the surrounding environment and reaching distant targets. They usually contain tight bundles of actin filaments.

Focal adhesions Cellular structures responsible for strong adhesion of cell to extracellular matrix. They are composed of a large set of signaling and adhesion molecules and often associated with actin stress fibers.

Lamellipodia Broad, flat, and thin cellular protrusions primarily responsible for the leading edge advance. They contain a dynamic network of branched actin filaments.

Myosin Large family of motor proteins capable of binding and moving along actin filaments. Individual myosins can be specialized for particular functions, such as contraction or transport of cargo.

Nucleation Initial slow phase of polymerization that involves thermodynamically unfavorable clustering of first few monomers. This cluster, or nucleus, then starts fast polymerization by incorporating additional monomers.

Sarcomere Repeating sections of myofibrils with a characteristic pattern of overlapping, contractile thick filaments (myosin) and thin filaments (actin) responsible for muscle contraction in skeletal or cardiac muscles.

Stress fibers Mixed bundles of actin and myosin-II filaments together with additional actin-associated proteins found in some nonmuscle cells. These fibers are usually attached to the extracellular matrix through focal adhesions and are responsible for generation of contractile force during cell migration and tissue morphogenesis.

Treadmilling Phenomenon of actin dynamics at which actin monomers incorporate at the barbed end of the actin filament and dissociate from its pointed end simultaneously. Treadmilling is possible due to lower critical concentration of actin addition to the barbed end than the pointed end and occurs when the ambient concentration of monomers is intermediate between two values.

Introduction

Actin is an abundant cytoplasmic protein that is able to assemble into polar filaments consisting of two strands of monomers twisted around each other. In cells, actin filaments undergo constant polymerization and depolymerization. Moreover, they usually function as an ensemble. These key features of actin behavior are regulated by numerous accessory proteins. Dynamic behavior of actin filaments is critical for their functions; therefore, all aspects of actin polymerization and depolymerization, such as nucleation, elongation, and disassembly, are tightly controlled in time and space by special proteins. Accessory proteins also help actin filaments to form higher-order structures, such as various networks and bundles, which differ in their properties, functions, and intracellular localization. Actin filaments frequently act in association with cellular membranes, which requires additional proteins. A collection of actin filaments with their associated proteins is usually referred to as the 'actin cytoskeleton'.

The actin cytoskeleton is the major force-generating machinery in the cell, which can produce pushing, pulling, and resistance forces. Actin filaments also serve as tracks for molecular motors of the myosin superfamily that mediate cargo delivery. The generation of pushing (or protrusive) forces involves coordinated polymerization of multiple actin filaments. Typical examples of actin polymerization-driven protrusion are the extension

of the cell plasma membrane during cell migration or shape change, and propulsion of membrane-enclosed organelles. Pulling (or contractile) forces are produced by the actin cytoskeleton in cooperation with myosin motors. The classic example of such activity is muscle contraction. Resistance forces are important for cell shape maintenance, for example, in biconcave red blood cells or in cylindrical cellular appendages, such as microvilli and stereocilia. The generation of resistance forces largely depends on activity of actin filament cross-linking proteins.

Actin Organization for Protrusion

General Concept

The actin cytoskeleton generates pushing force using energy of actin polymerization. The directionality of force originates from the structural polarity of actin filaments, in which one end (barbed or plus end) undergoes faster dynamics than the other (pointed or minus end). The filament polarity is further enhanced by time-dependent hydrolysis of the actin-bound adenosine triphosphate (ATP) after monomer incorporation into the filament. Due to structural and biochemical differences, the barbed end of a filament can grow while the pointed end shrinks, a process called 'treadmilling' (Figure 1). The intrinsic treadmilling of actin filaments is greatly augmented in cells by regulatory proteins, primarily by profilin and actin

Figure 1 Actin filament treadmilling. Polymerization of the actin filament preferentially occurs at the barbed end from ATP-actin/profilin complexes, which dissociate releasing profilin after incorporation of the actin monomer into the filament. Polymerization-triggered ATP hydrolysis and subsequent phosphate release in assembled actin subunits make filaments more susceptible to depolymerization and increase their affinity for ADF/cofilin. ADF/cofilin severs filaments promoting their depolymerization. Released actin subunits are recycled when profilin competes off ADF/cofilin and promotes nucleotide exchange in the actin monomer.

depolymerizing factor (ADF)/cofilin. Profilin binds the barbed end surface of actin monomers precluding their interactions with pointed ends of monomers or polymers. This directs filament elongation toward barbed ends and prevents spontaneous filament nucleation. ADF/cofilin binds laterally to actin filaments and causes their severing, thus exposing additional ends susceptible to depolymerization. Preferential binding of ADF/cofilin to adenosine diphosphate (ADP)-containing actin subunits leads to accelerated depolymerization of the older parts of the filament located closer to the pointed end.

Intrinsic actin filament treadmilling lies at the core of the concept of pushing force generation. In cells, pushing actin filaments are uniformly oriented with their barbed ends toward the load, commonly, the plasma membrane or a membrane organelle. While elongating barbed ends push on the load, disassembly occurs closer to the pointed ends, releasing monomers for recycling. Although this concept is well conserved among cells and across biological processes, the specific design of actin polymerization machinery varies. In general, individual actin filaments are too weak to produce large forces. Therefore, they usually act as a cohort of interconnected filaments, which allows them to achieve necessary stiffness. The main strategies of coordinating polymerization of multiple filaments are the formation of parallel bundles and branched networks.

Protrusion of Actin Filament Bundles

The first example of membrane protrusion driven by elongating actin filament bundles was the acrosome reaction in echinoderm sperm, which was also the original discovery of the actin polymerization-dependent force generation. An initial contact of a sperm cell with an egg leads to explosive extension of a long acrosomal process from the sperm head, which helps the sperm to penetrate the egg jelly. The extension of the process correlates with the growth of an internal actin filament bundle consisting of actin filaments uniformly oriented with their barbed ends toward the tip. Polymerization stops when the available pool of monomers is used up.

The molecular machinery of treadmilling actin bundles is best studied in filopodia, which are needle-like protrusions at the leading edge of migrating cells (Figure 2). Individual

actin filaments in the filopodial bundles are uniformly oriented with barbed ends toward the tip and span the entire length of filopodia. During protrusion, actin subunits are incorporated at the tips, move away from the tip as a part of the filament lattice, and are released at the rear of filopodia. Slow intrinsic treadmilling of actin filaments is accelerated in filopodia by proteins controlling elongation, cross-linking, interaction with the membrane, and disassembly of actin filaments. Elongation is assisted by two distinct families of barbed end-binding proteins, formins and Ena/vasodilator-stimulated phosphoprotein (VASP) proteins. Although unrelated genetically or biochemically, both classes of proteins allow for incorporation of new actin subunits without dissociating from the barbed end. Elongation is accelerated because these proteins bind profilin, through which they recruit multiple profilin-actin complexes and increase the local concentration of actin subunits near the barbed end. In addition, both formins and Ena/VASP proteins prevent binding of capping proteins to the barbed ends, which would terminate elongation, and keep the elongating ends near the membrane to increase efficiency of pushing. Filopodia elongation is also promoted by myosin X, which likely delivers actin subunits and/or regulators of polymerization to filopodial tips using its motor activity. The intrinsically slow dissociation of actin subunits from the pointed ends cannot account for maintaining the steady state of fast protruding filopodia. Two actin filament severing proteins, ADF/cofilin and gelsolin, are believed to facilitate depolymerization by increasing the number of exposed pointed ends. Myosin II, which breaks filaments by applying a pulling force on them, also contributes to this process. Cross-linking of actin filaments in filopodia increases the stiffness of the bundle, thus allowing it to overcome the membrane resistance and prevent buckling during protrusion. The major cross-linker in filopodia is fascin, a bivalent monomeric protein. Lateral binding of filopodial bundles to the plasma membrane helps maintain the shape of filopodia. It is likely mediated by proteins of the ezrin-radixin-moesin (ERM) family, which bind both actin filaments and membrane components, phospholipids and transmembrane proteins. Specific membrane-deforming proteins, such as IRSp53, also play positive roles in filopodia protrusion by stabilizing the

Figure 2 Actin organization in filopodia. (a) Typical actin structures in a migrating fibroblast-like cell. Protrusive organelles, lamellipodia and filopodia, are located at the cell leading edge. (b) Platinum replica transmission electron microscopy of a filopodium at the leading edge of a mouse melanoma cell. Boxed region is enlarged in the right panel and shows long parallel actin filaments. (c) Molecular organization of filopodia. Actin filaments are oriented with barbed ends toward the filopodial tip. They are bundled by fascin and laterally attached to the plasma membrane by ERM proteins. Formin and/or Ena/VASP proteins associate with the barbed ends, promote their elongation, and anchor to the membrane at the tip. Unconventional myosin X moves along actin filaments and accumulates at the filopodial tips (not shown).

tubular shape of the filopodial membrane and by indirectly linking it to the actin cytoskeleton.

Protrusion of Branched Networks

The assembly of branched actin filament networks provides pushing force for multiple cellular events, the best studied of which are protrusion of lamellipodia at the leading edge of migrating cells (Figure 3) and rocketing motility of certain intracellular pathogens, such as *Listeria monocytogenes*. In addition, branched networks promote various endocytic events, motility and biogenesis of intracellular organelles, and the formation of diverse cell–cell junctions including neuronal and immune synapses.

Protrusion of branched networks involves continuous nucleation of new actin filaments at the side of pre-existing filaments in the process called ‘dendritic nucleation’. The nascent filaments elongate and produce force while they are short and stiff. Their elongation is then terminated by barbed end capping, while new filaments are nucleated to maintain protrusion. Being anchored to pre-existing filaments and, consequently, to the entire branched network, nascent filaments can efficiently transform the energy of polymerization into useful work, rather than push themselves away from the load. Filaments are nucleated at a defined angle of 70° , which allows the network to expand or reorient itself by simply adjusting the rates and sites of nucleation and capping. At steady state, nucleation of new filaments is balanced by capping of old filaments at equivalent rate. The recycling of actin monomers is mediated by disassembly of the network through a combination of debranching and severing followed by depolymerization of filament fragments. Branched networks disassemble throughout their volume except for the very front, where actin filaments are enriched in ATP-loaded subunits. Thus, the branched network as a whole, but not individual filaments,

undergoes treadmilling by assembling at the front and, on average, disassembling at the rear.

The assembly of branched networks of actin filaments requires several accessory molecules. A heteromeric complex of seven proteins, the Arp2/3 complex, is responsible for key events in this process: it nucleates filaments, links them to the pre-existing filaments at the defined angle of 70° , and caps the pointed end of the new filament to prevent its premature depolymerization. The intrinsically inactive Arp2/3 complex is activated by nucleation-promoting factors, primarily by the Wiskott–Aldrich syndrome protein (WASP) family proteins, which are recruited to the working interface, such as the plasma membrane or a particle. This allows the nucleation to occur, and therefore force to be generated, right where it is needed. Barbed end capping is mediated by the heterodimeric capping protein, which tightly binds the barbed end and prevents its dynamics. ADF/cofilin plays a key role in depolymerization of branched networks. The activated Arp2/3 complex, capping protein, and ADF/cofilin represent the minimal molecular toolbox required for steady-state treadmilling of branched networks. Many other molecules improve the performance of this machinery in a living cell. Thus, profilin prevents spontaneous nucleation and targets monomers to the barbed ends, formins and Ena/VASP proteins transiently protect elongating ends from capping and processively anchor them to the membrane, the actin-binding protein cortactin stabilizes branches, the cross-linkers filamin A and α -actinin consolidate the whole network, and numerous molecules regulate all these proteins.

Actin Organization for Contraction

General Concept

Pulling forces are generated by the actin cytoskeleton in cooperation with myosin motors. Myosins are a large superfamily

Figure 3 Actin organization in lamellipodia. (Top) Platinum replica transmission electron microscopy of a lamellipodium at the leading edge of a fish epidermal keratocyte. Boxed region is enlarged in the right panel and shows branched actin filaments. (Bottom) Molecular organization of lamellipodia. The Arp2/3 complex is cooperatively activated by a membrane-targeted nucleation-promoting factor and a pre-existing actin filament. Upon activation, it nucleates a new actin filament at the side of the pre-existing filament and remains associated with the branch point. Branch points are further stabilized by cortactin. The nascent filament elongates with its barbed end oriented toward the membrane. Its elongation is promoted by formins and/or Ena/VASP proteins. After a period of elongation, the barbed end is capped by capping protein and lags behind the protruding leading edge. Disassembly at the rear of the lamellipodial network occurs through dissociation of branches and ADF/cofilin-mediated severing.

Figure 4 Myosin II motor activity. Myosin II hexamer consisting of two heavy chains and two pairs of light chains moves toward the barbed end of the actin filament by swinging its motor domain in an ATP-dependent manner.

of motor proteins, which are able to convert chemical energy of ATP into mechanical work (Figure 4). The myosin molecule consists of one or two heavy chains containing a motor domain and a cargo-binding tail, and a variable number of light chains. Cycles of ATP binding, hydrolysis, and release of hydrolytic products by the motor domain are coupled to specific and sequential changes in the myosin conformation and affinity for actin filaments, which allow myosin to move and translocate cargo along actin filaments, or to pull on the actin filament. The majority of myosins, with the notable exception of myosin VI, move toward the barbed ends of the actin filament.

Class II myosins are specifically designed to mediate cell contraction. In contrast to other myosins, myosin II polymerizes into bipolar filaments through antiparallel interactions between their coil-coiled tail domains, so that the motor domains are located at both filament ends. When presented to actin filaments of opposite polarity, bipolar filaments cause contraction by pulling on actin filaments from both sides in opposite directions. This concept of actin–myosin-mediated contraction, the sliding filament model, was proposed independently by Hugh Huxley and Andrew Huxley in 1954 based on their studies of skeletal muscle contraction. Other cells utilize the same principle of mutual sliding of actin and myosin II filaments, but in a less ordered and more dynamic fashion.

In contrast to actin polymerization-driven processes, actin filaments in contractile systems should be relatively stable to provide reliable tracks for myosin motors, while actin dynamics is needed primarily for renewal of aged or damaged filaments. Stabilization of actin filaments is mediated by capping proteins blocking dynamics at the ends, and by tropomyosins stabilizing filaments along their length. Tropomyosin is a long dimeric coiled-coil protein that sits in the groove between two strands and binds seven consecutive subunits in the actin filament, without interfering with myosin movement. Correct spatial organization of actin filaments is also crucially important for the functionality of contractile systems. It is controlled by cross-linking proteins, especially by α -actinin, and by system-specific proteins anchoring the actin filaments to the load.

Striated Muscle Contraction

The cellular contractile machinery in striated (skeletal and cardiac) muscles appears to have evolved to perfection. It consists of highly ordered arrays of actin and myosin filaments efficiently generating contractile force. The minimal functional unit in striated muscles is the sarcomere (Figure 5). A multinuclear muscle cell (muscle fiber) contains multiple longitudinally connected sarcomeres separated by Z-lines. A set of actin (or thin) filaments of uniform length and polarity is attached to the Z-line on each side of the sarcomere. The barbed ends of actin filaments are embedded into the Z-line and capped by heterodimeric capping protein, which in muscle is called 'CapZ'. Pointed ends are located close to the middle of the sarcomere and are capped by the pointed end capper, tropomodulin. Tropomyosin additionally stabilizes actin filaments along their length. Another protein laterally bound to actin filaments, nebulin, is thought to control actin filament length. The regular spacing between actin filaments is defined by α -actinin, located at Z-lines. Bipolar filaments composed of the skeletal muscle myosin II (thick filaments) are suspended in the middle of the sarcomere and their ends interdigitate with actin filaments in both halves of the sarcomere. The regular arrangement of myosin II filaments is maintained by proteins of the M-line, a structure in the exact center of the sarcomere, and by the giant protein titin, which extends from the M-line to the Z-line along each myosin filament. The motor domains of myosin filaments interact with actin filaments, forming cross-bridges structurally recognizable by electron microscopy. Translocation of myosin motor domains toward the barbed ends of actin filaments on each side of the sarcomere shortens individual sarcomeres which, given their serial organization, contracts the entire cell.

Regulation of muscle contraction is primarily mediated by Ca^{2+} . When an action potential arrives from the motor neuron, it opens calcium channels in the membrane of the sarcoplasmic reticulum through a series of intermediate events and causes a sudden increase in the Ca^{2+} concentration in the muscle fiber. A calcium-sensing regulatory element in the sarcomere is the troponin complex consisting of troponins I, T,

Figure 5 Actin organization in striated muscles. (Top) Thin section transmission electron microscopy image of frog sartorius muscle shows sarcomeric organization of muscle fibers. One full sarcomere is present in the image. (Bottom) Molecular organization of the sarcomere. Black lines connect corresponding zones in the micrograph and the diagram. and C. The troponin complex binds both actin and tropomyosin and regulates the positioning of tropomyosin on actin filaments in a Ca^{2+} -dependent manner. In the absence of Ca^{2+} , tropomyosin moves out of its normal position in the groove on the actin filament and blocks the myosin–actin interaction. In the presence of Ca^{2+} , when the inhibitory interaction between actin, troponin, and tropomyosin is released, tropomyosin moves back into the groove, allowing myosin to move.

Smooth Muscle Contraction

The spatial organization and the mechanism of contraction of smooth muscle cells are still poorly understood. Smooth muscle cells do not have sarcomeric organization and appear to combine features of striated muscle fibers and nonmuscle cells. Instead of Z-lines, barbed ends of actin filaments in smooth muscle cells associate with α -actinin-rich dense bodies scattered through the cytoplasm or bound to the plasma membrane and interconnected by intermediate filaments. Smooth muscle isoforms of myosin II polymerize into side-polar filaments, instead of bipolar filaments, of variable lengths.

Side-polar myosin II filaments lack a bare zone in the middle, so that myosin heads project from the filament shaft all along the length, but change polarity on each side of the filament. The actin and myosin filaments in smooth muscle cells are only roughly aligned with the longitudinal axis of these spindle-shaped cells. Sliding of myosin II filaments along actin filaments causes contraction due to extensively interconnected filamentous network in the cell.

The regulation of smooth muscle contraction relies on phosphorylation-dependent changes of myosin II activity, rather than on troponin-dependent repositioning of tropomyosin, although both are regulated by Ca^{2+} . Smooth muscle myosin II is active when one of its associated light chains, the regulatory light chain, is phosphorylated. Phosphorylation is mediated primarily by myosin light chain kinase (MLCK), which is activated by Ca^{2+} . When light chains are not phosphorylated, the smooth muscle myosin has very low actin-activated adenosine triphosphatase (ATPase) activity in its motor domains. Also, it cannot form filaments under this condition, because its tail bends and interacts with the motor domains. Phosphorylation of the regulatory light chain causes unfolding of the molecule, activation of the ATPase activity,

Actin filaments (orange) form a diagonal network with barbed ends to the front (top). Myosin bipolar filaments (purple) that initially are randomly bound to actin filaments move toward barbed ends causing network contraction and mutual orientation of actin and myosin filaments. At the next step, the newly formed bundle will contract longitudinally.

formation of myosin II filaments, and muscle contraction. Conversely, relaxation of smooth muscles requires low calcium and phosphatase activity.

Contraction of Nonmuscle Cells

Many nonmuscle cells are able to generate substantial contractile forces that are used for morphogenesis, cytokinesis, rearrangement of extracellular matrix, and formation of cell–cell and cell–matrix junctions. For contraction, nonmuscle cells use mixed bundles and networks of actin and myosin filaments. Nonmuscle myosin II forms very short bipolar filaments ($\sim 0.3 \mu\text{m}$) and is regulated similar to smooth muscle myosin II. However, many more kinases, besides MLCK, can phosphorylate nonmuscle myosin II on the regulatory light chain. Activation of these kinases occurs in response to various

signals, with the most important ones being Ca^{2+} and Rho family guanosine triphosphatases (GTPases).

Contractile bundles of nonmuscle cells, or stress fibers (Figures 2, 6(a), and 6(b)), are best studied in fibroblasts, which are mesenchymal cells engaged in secreting and remodeling the extracellular matrix. Stress fibers consist of aligned actin and myosin filaments and are attached to the extracellular matrix through transmembrane integrin receptors at special attachment sites called 'focal adhesions'. Focal adhesions are very complex structures that contain α -actinin among many other structural and signaling proteins. At focal adhesions, actin filaments are uniformly oriented with their barbed ends toward the plasma membrane, but they are not capped, as in sarcomeres, and can elongate. Away from focal adhesions, actin filaments in stress fibers have mixed polarity. Myosin bipolar filaments are arranged in a semi-periodic fashion along the length of the stress fiber, where they colocalize with

tropomyosin, whereas intervening areas are enriched in α -actinin. This organization is distantly related to that seen in striated muscle sarcomeres, although in a considerably less ordered fashion, given that myosin filaments are not perfectly aligned across the stress fiber and are unevenly spaced along the stress fiber. Actin filaments also have variable lengths and may pass through several myosin-rich regions. Contraction in stress fibers, like in other contractile cells, involves mutual sliding of actin and myosin filaments. Productive contraction likely occurs when myosin motors interact with nearby actin filaments of appropriate orientation.

In order to mediate contraction, actin and myosin filaments do not have to be aligned, but may be arranged into a network, in which individual filaments are oriented at a range of angles (Figures 6(c) and 6(d)). If actin filaments are attached at their barbed ends, as is usually the case in cells, movement of two ends of a myosin filament toward randomly oriented barbed ends produces mutual alignment of actin and myosin filaments between the major attachment sites, and fosters a network contraction in the perpendicular direction. This mechanism is responsible, for example, for the translocation of the cell body in fish epidermal keratocytes, and for initial formation of stress fibers in fibroblasts. It also likely plays a role in other less understood contractile events in nonmuscle cells.

structures except for that needed for their renewal. Association of these actin ensembles with the plasma membrane is required to translate their mechanical properties into a specific cell shape.

Actin filament cross-linking proteins use two or more actin-binding sites to bring actin filaments together. Some cross-linkers, such as fascin, fimbrin (I-plastin), and espin, have two actin-binding sites within one polypeptide. Others, such as α -actinin and filamin, readily form homodimers with one actin-binding site per subunit. Spectrin is a long flexible heterotetramer with two actin-binding sites at the opposite ends of the molecule. Myosin II filaments can also function as multivalent cross-linkers when they do not use their motor activity, or use it in an isometric mode. The distance between actin-binding sites along with the flexibility of spacers determines the geometry and mechanical properties of resulting actin filament ensembles. Thus, the short spacing between actin-binding sites in fascin, espin, or fimbrin produces stiff and tightly packed bundles of actin filaments. The longer spacer present in α -actinin keeps cross-linked actin filaments farther apart to allow for the movement of myosin filaments, but it is still narrow enough to align filaments into bundles. Cross-linkers with significantly distant actin-binding sites, such as spectrin and filamin, foster the formation of loose elastic networks.

Actin Organization for Shape Determination

General Concept

Cells extensively use the actin cytoskeleton to define their shape and resist environmental stresses. Although protrusive and contractile forces and junctions with other cells and matrices are intrinsic parts of the cell shape determination by the actin cytoskeleton, some actin structures are designed just to resist external forces. Individual actin filaments are relatively weak and too unstable for this function, but they form strong and stable ensembles when interconnected by cross-linking proteins. Actin dynamics is also usually suppressed in such

Shape Determination by Elastic Networks

The best-studied example of cell shape determination by elastic networks is the actin–spectrin membrane skeleton in red blood cells, which is responsible for the characteristic biconcave shape of these cells and their ability to withstand significant shear stresses in the circulation (Figure 7). Spectrin, rather than actin itself, is the major structural component of this network. Long and flexible spectrin tetramers form a triangular mesh, in which very short actin filaments (~ 13 monomers long) join ends of up to six spectrin molecules at each node forming the so-called junctional complex. Each actin filament is stabilized

Figure 7 Membrane skeleton in red blood cells. The actin–spectrin network is attached to the plasma membrane through two major anchors, ankyrin and band 4.1, which associate with transmembrane proteins, glycophorin and band 3.

along its length by tropomyosin and is capped by tropomodulin and adducin at the pointed and barbed ends, respectively. Connection of the actin-spectrin mesh to the membrane is mediated by several anchors, the most important of which are band 4.1 and ankyrin. Band 4.1 binds both actin and spectrin at the junctional complex and stabilizes their interaction. Simultaneously it interacts with the plasma membrane through membrane phospholipids and transmembrane proteins, band 3 (anion exchanger) and glycophorin. Ankyrin binds the middle of the spectrin tetramer and links it to band 3 in the plasma membrane. Similar actin-spectrin networks also function in nonerythroid cell types, where they use many of the same, or homologous, proteins to maintain the membrane integrity and define its physical properties.

Shape Determination by Stiff Bundles

Stiff actin filament bundles play important roles in the elaboration of cylindrical cell surface protrusions, the best-understood examples of which being microvilli in the intestinal epithelium and stereocilia in the hair cells in the inner ear.

Microvilli are nonmotile finger-like protrusions from the apical surface of epithelial cells that function to increase the cell surface area and the efficiency of absorption. Microvilli have uniform length (1–2 μm) and thickness (~ 200 nm) and are tightly packed next to each other forming a special compartment of the cell called the 'brush border'. The shape of microvilli is maintained by an internal bundle of ~ 20 – 30 parallel actin filaments. The bundle is structurally similar to that occurring in filopodia, but exhibits approximately threefold slower dynamics. The actin filament barbed ends located at the tips of microvilli are embedded into a material of unknown composition, which likely regulates their dynamics. The main cross-linkers in the bundle are fimbrin and villin, a gelsolin-family severing protein with bundling activity. The actin bundle is laterally attached to the plasma membrane by monomeric myosin Ia, which binds actin filaments by its motor domain and acidic phospholipids in the plasma membrane by its tail. Myosin Ia is fully functional as a motor and is believed to regulate membrane tension around microvilli. Microvilli are also present on the surface of other cell types, such as other epithelial cells, lymphocytes, and various sensory cells. However, the main cross-linkers in sensory cell microvilli are fimbrin and espin, whereas villin is specific for epithelial cells.

Stereocilia are specialized mechanosensory microvilli involved in hearing and the sense of balance. They differ from microvilli by their size, shape, dynamics, and molecular composition. Stereocilia lengths vary from 1 to 100 μm , but are tightly controlled to match the frequency of sound waves to be detected. Stereocilia have ~ 10 -fold more actin filaments in their core bundle than microvilli. They also undergo ~ 100 -fold slower dynamics. Actin filaments are cross-linked by fimbrin

and espin, as in sensory, but not intestinal, microvilli. In contrast to fully cylindrical microvilli, stereocilia taper toward the bottom, which allows them to pivot around the base in response to vibration while remaining straight. Unconventional myosins Ia, Ic, IIIa, VI, VIIa, and XVa, have been functionally implicated in hearing by contributing to stereocilia structure. Myosins IIIa and XVa localize to stereocilia tips, like myosin X in filopodia, and contribute to length determination in a complementary fashion. Myosins Ia, Ic, and VIIa are present along the length of the stereocilia, similar to myosin Ia in microvilli, and may also regulate membrane tension. Myosin VI is present at the tapered base of stereocilia, and is thought to deliver actin regulators to these sites.

Glossary

Actin Ubiquitous, eukaryotic cytoskeletal protein. Actin monomers assemble into filaments that are used to organize the intracellular space and to define the shape and mechanical properties of eukaryotic cells.

Adenosine triphosphate (ATP) It is the major energy currency of living cells. The removal or hydrolysis of phosphates from ATP releases energy that individual proteins can use to do work.

Chromatin DNA that has been packaged and compacted by specialized proteins, called histones. The packaged DNA must be partially unpackaged (by chromatin remodeling complexes) to allow transcription of genes.

Cytoskeleton A network of protein polymers that organize the intracellular space; transport intracellular cargos;

determine cell shape; and drive cell locomotion.

The three most important eukaryotic cytoskeletal polymers are actin filaments, microtubules, and intermediate filaments.

Eukaryote A cell with a nucleus and other membrane-bound organelles.

Histones DNA-packaging proteins. In compacted chromatin, DNA is wound around histones like thread around a spool.

Primary sequence The sequence of amino acids that comprise a protein. Usually given from amino to carboxy terminus.

Prokaryote A simple cell, such as a bacterium, that lacks a nucleus and other intracellular compartments.

Actin-related proteins (Arps) are a class of proteins found in all eukaryotes and many species of bacteria and archaea. Arps are defined by their degree of similarity to actin (conventional actin), a ubiquitous, eukaryotic cytoskeletal protein. All Arps are built around a common structural fold. This actin fold binds and hydrolyzes adenosine triphosphate (ATP). In most Arps, ATP hydrolysis is converted into a conformational change that regulates assembly and/or function of multiprotein complexes. Conventional actin assembles into two-stranded helical filaments that form structural scaffolds used to organize the intracellular space and to drive cell division, shape change, and cell locomotion. Eukaryotic Arps fall into 10 groups (Figure 1 and Table 1) that can be loosely grouped into two categories: (1) cytoskeleton-associated Arps (Arp1, Arp2, Arp3, and Arp10) that regulate the assembly and function of the actin and microtubule cytoskeletons; and (2) chromatin-associated Arps (Arp4–Arp9) that regulate the structure and function of eukaryotic chromatin. Prokaryotic Arps were discovered only recently and their functions are not well understood. The best-characterized prokaryotic Arps (MreB, Mbl, and the plasmid-encoded protein, ParM) polymerize into filaments required for proper cell shape and DNA segregation. The primary sequences of prokaryotic Arps are highly divergent from those of the eukaryotic Arps but we include them in this discussion based on the similarity of their biochemical activities and cellular functions to conventional actin and the eukaryotic Arps. The presence of Arps in chromatin-remodeling complexes and the importance of prokaryotic Arps in DNA segregation suggest that their role in the handling of DNA is as ancient and well conserved as their more well-known cytoskeletal functions.

The Actin Fold

There is little or no conservation of surface-exposed residues among Arps. This reflects the fact that the proteins in this family have different binding partners and cellular functions (Figure 1 and Table 1). All Arps, however, share a common structural fold. The core of the protein is formed from two globular domains (domain I and domain II) connected by a flexible hinge (Figure 2(b)). The interface between the two domains forms an ATP-binding pocket. Five highly conserved sequences – three ATP-binding loops and two connecting helices – line this pocket and define the actin fold. These sequences are an adenosine-binding loop (adenosine), two phosphate-binding loops (phosphate 1 and phosphate 2), and two connecting domains (connect 1 and connect 2). These sequences are conserved in actin, the Arps, and all other members of the actin superfamily (which includes proteins like hexokinase and HSP70) and they are always arranged in the following order: phosphate 1, connect 1, phosphate 2, adenosine, and connect 2 (Figure 2(a)). The ATP-binding loops are distributed between the two domains of the protein. Phosphate 1 is located in domain I and both phosphate 2 and adenosine are in domain II (Figure 2(b)). When all three loops interact with ATP the two domains are tightly associated. Hydrolysis of the gamma phosphate of ATP weakens binding to the phosphate 1 domain and causes the two domains of the protein to swing apart around the hinge formed by connect 1 and connect 2. Complete loss of nucleotide results in further opening of the protein around the hinge. In some members of the actin superfamily the binding of ATP to a nucleotide-free protein causes the domains to rotate by 30° around the hinge region (Figure 2(c)).

Figure 1 The eukaryotic Arp family is composed of 10, highly conserved members. Members fall broadly into two categories: cytoskeletal Arps (conventional actin, Arp1, Arp2, Arp3, and Arp10) and nuclear Arps (Arp4, Arp5, Arp6, Arp7, Arp8, and Arp9). The diagram is an unrooted phylogenetic tree of the actin superfamily. Reprinted from Goodson HV and Hawse WF (2002) Molecular evolution of the actin family. *Journal of Cell Sciences* 115(Pt 13): 2619–2622. Calculated by Thompson JD, Gibson TJ, Plewniak F, Jeanmougin F, and Higgins DG (1997) The CLUSTAL_X windows interface: Flexible strategies for multiple sequence alignment aided by quality analysis tools. *Nucleic Acids Research* 25(24): 4876–4882.

The shift from closed to open conformation is used by Arps to regulate their interactions with other proteins.

Prokaryotic Arps

An actin cytoskeleton is thought to be a prerequisite for the establishment and maintenance of intracellular compartments and organelles and until recently actin was thought to be a strictly eukaryotic protein. Recent work, however, has identified actin-like proteins in prokaryotes. The first two prokaryotic actin-like proteins, MreB and Mbl, were discovered in *Bacillus subtilis*. These proteins have very limited primary sequence similarity to conventional actin but, remarkably, they fold into three-dimensional structures very similar to actin and, like conventional actin, they polymerize into two-stranded filaments in a manner that depends on ATP and salt. At present

not much is known about the cellular roles of MreB and Mbl, but they do appear to form filaments *in vivo* that are required for proper positioning of the cell-wall synthesis machinery and proper shape determination of rod-shaped bacteria. In addition, MreB and Mbl are required for proper segregation of bacterial DNA during cell division. These are the types of functions performed by polymeric cytoskeletal elements in eukaryotes so it is fair to say that MreB and Mbl form a bona fide bacterial cytoskeleton.

Another remarkable prokaryotic actin-like protein is encoded by the *parM* locus of the low-copy drug-resistance plasmid, R100. The R100 plasmid is stably maintained at one copy per cell in bacterial populations because it accurately segregates one copy each into daughter cells during each cell division. Three plasmid loci are required for this accurate segregation: *ParR*, *parM*, and *ParC*. *ParR* encodes a DNA-binding protein that binds tightly to the *ParC* locus. *parM* encodes an actin-like

Table 1 Cellular localization, function and multiprotein complexes of eukaryotic Arps

Arp	Sequence similarity to actin	Cellular localization	Function	Multiprotein complexes
Actin	100% ident. 100% simil.	Cell cortex, leading edge, stress fibers, endosomes, vesicles, nucleus	Cell shape and motility, intracellular trafficking, chromatin remodeling (?), histone acetylation (?)	Actin filaments, INO80, BAF, and NuA4 complexes
Arp1	45% ident. 68% simil.	Golgi apparatus, transport vesicles, centrosomes, cell cortex	Dynein-driven intracellular movements	Dynactin complex
Arp2	45% ident. 69% simil.	Cell cortex, leading edge, some motile endosomes	Actin filament nucleation and cross-linking	Arp2/3 complex
Arp3	39% ident. 60% simil.	Cell cortex, leading edge, some motile endosomes	Actin filament nucleation and crosslinking	Arp2/3 complex
Arp4	30% ident. 53% simil.	Nucleus	Histone acetylation, chromatin remodeling, control of transcription	NuA4 and INO80 complexes
Arp5	26% ident. 51% simil.	Nucleus	Chromatin remodeling, control of transcription	INO80 complex
Arp6	24% ident. 46% simil.	Nucleus	Unknown	Unknown
Arp7	22% ident. 44% simil.	Nucleus	Chromatin remodeling, control of transcription	Swi/Snf and RSC complexes
Arp8	21% ident. 44% simil.	Nucleus	Chromatin remodeling, control of transcription	INO8 complex
Arp9	17% ident. 40% simil.	Nucleus	Chromatin remodeling, control of transcription	Swi/Snf and RSC complexes
Arp10	17% ident. 38% simil.	Golgi apparatus, transport vesicles, centrosomes, cell cortex	Dynein-driven intracellular movements	Dynactin complex

protein that assembles into two-stranded filaments in an ATP-dependent manner. The ParR protein bound to the ParC locus appears to nucleate formation of *parM* filaments, which drive plasmid segregation. This simple three-piece system may form a structure functionally equivalent to a mitotic spindle and may represent the minimal system for segregating DNA. Unlike conventional actin filaments in which ATP hydrolysis regulates interaction with depolymerizing factors (**Figure 3(b)**), ATP binding and hydrolysis directly control assembly and disassembly of ParM filaments. ATP-bound monomers polymerize into filaments. Within the filament, monomers hydrolyze ATP to adenosine diphosphate (ADP). ADP-bound filaments then rapidly disassemble (**Figure 3(a)**).

Eukaryotic Arps

Cytoskeletal Arps

We briefly discuss conventional actin, which is well described in a separate article on actin dynamics in this encyclopedia. Arp1 and Arp10 are part of a dynein-activating (dynactin) complex that regulates activity of the microtubule motor protein dynein. Arp2 and Arp3 are subunits of the Arp2/3 complex – a protein complex that nucleates formation of new actin filaments in response to upstream signaling events (see **Table 1**).

Conventional actin

Actin is one of the most abundant and highly conserved proteins in eukaryotes. In motile cells, actin is typically the most abundant cellular protein and is present at concentrations of 100–200 μM (or 5–10% of total cellular protein). Protozoans,

such as budding and fission yeast and slime molds, generally express one isoform of actin. Metazoans typically express multiple, tissue-specific isoforms. Humans express at least six isoforms of actin: two striated muscle isoforms (α -skeletal and α -cardiac), two smooth muscle isoforms (α -smooth muscle and α -enteric), and two widely expressed cytoplasmic isoforms (β -cytoplasmic and γ -cytoplasmic). The α -skeletal and α -cardiac striated muscle isoforms are expressed specifically in muscle tissues where they form arrays of thin filaments that interdigitate with thick filaments composed of the motor protein myosin. Sliding of the thick and thin filaments past each other drives contraction of the muscle tissue. The thin filaments in muscle tissues are very stable structures whose architecture does not change much over time. The smooth muscle actins form less organized filament arrays involved in contraction of vascular and enteric smooth muscle. The cytoplasmic β - and γ -isoforms are the most widely expressed and form much more dynamic cytoskeletal structures. The β -isoform is ubiquitously expressed and is responsible for building the contractile ring that divides cells at the end of mitosis and for most actin-based intracellular traffic. The assembly of β -cytoplasmic actin also drives cell spreading and the amoeboid, or crawling, motility of many cell types, including those of the nervous and immune systems. The β -isoform is most closely related to protozoan actins. The γ -cytoplasmic isoform is expressed in many different cell types but it is much less abundant than β -cytoplasmic actin. The specific function of γ -actin is unknown.

The defining property of conventional actin is its self-assembly into helical polymeric filaments. Monomeric actin binds ATP with high (nanomolar) affinity but does not hydrolyze it. The transition from monomer to polymer

Figure 2 Organization and structure of Arps and the conformational changes driven by ATP binding and hydrolysis. (a) Organization of conserved sequences that define the ATP-binding pocket of the actin fold. Ph1 and Ph2: phosphate-binding loops. C1 and C2: connecting domains. Ad: adenosine-binding domain. The order of these sequences is the same in the primary amino acid sequence of all actin-related proteins. (b) Atomic structure and domain organization of an actin monomer. The atomic structure of actin (left) is shown with a bound ATP molecule (green) and with ellipses identifying the two large domains – domain I and domain II – that define the ATP-binding pocket. The phosphate- and adenosine-binding sequences line the interface between domain I and domain II and interact with the ATP molecule (right). The connecting sequences (C1 and C2) link the two protein domains and act as a hinge. (c) Nucleotide-dependent conformational changes in the actin fold. ATP binding holds the domain I and domain II tightly together (ATP, left). Hydrolysis of the γ -phosphate of ATP to form ADP weakens the interaction with one of the phosphate-binding loops (Ph1) and causes the cleft between the domains to open (ADP, center). Loss of nucleotide from the binding pocket causes the cleft to open even further (Apo, right). Actin-related proteins use this conformational change to regulate their interactions with other proteins.

stimulates the hydrolysis of ATP. Hydrolysis is not required for polymerization but rather for depolymerization. Cleavage of the γ -phosphate and its subsequent dissociation trigger a conformational change that enables binding of actin-depolymerizing factors such as ADF or cofilin (Figure 3(b)).

Arp1

Arp1 is most closely related to conventional actin and, like actin, it assembles into a filamentous polymer. Arp1 forms part of a large (1.2 MDa) protein complex that modulates the activity of the microtubule motor protein dynein. Within the dynactin complex, ~10 Arp1 molecules assemble to form a short (37 nm), actin-like filament. This short filament functions as a scaffold that connects dynein motors to cargo vesicles. The Arp1 filaments bind an isoform of the actin-binding

Figure 3 Regulation of actin and Arp function by ATP hydrolysis. The relationship between ATP hydrolysis and protein–protein interactions is best understood in the cytoskeletal Arps. (a) When bound to ATP the plasmid-encoded Arp, ParM (green circles), polymerizes into actin-like filaments. Polymerization induces hydrolysis of bound ATP (red arrow); and the ADP ParM filaments (red circles) undergo a conformational change that causes them to rapidly fall apart. (b) Conventional actin and Arp1 (green circles) polymerize into similar two-stranded helical filaments. Polymerization induces ATP hydrolysis on both proteins (red arrow) but the filaments do not spontaneously disassemble. In the case of conventional actin, a conformational change in the ADP filament structure (red circles) promotes binding of actin depolymerization factors (white wedges), which drive filament disassembly. (c) As part of the Arp2/3 complex, Arp2 and Arp3 bind ATP (green circles are ATP-bound Arp2 and Arp3) and nucleate formation of new actin filaments. The nucleation reaction requires monomeric actin and a pre-formed actin filament (black circles) and an Arp2/3 activator (black hook). Assembly of these cofactors induces ATP hydrolysis on Arp2 and promotes a conformational change in the Arp2/3 complex that converts it into a filament nucleus.

protein spectrin that is specific for the Golgi apparatus and for Golgi-derived vesicles. Arp1 and Golgi spectrin are thought to assemble into a membrane-associated meshwork that surrounds vesicles like a cargo net and allows dynein motors to move them around inside the cell.

In vitro, purified Arp1 polymerizes into short filaments indistinguishable from conventional actin filaments. Arp1 hydrolyzes ATP upon polymerization but this does not have a dramatic effect on filament stability *in vitro*. Like actin, Arp1 may hydrolyze ATP to modulate its affinity for an accessory factor required for filament disassembly (Figure 3(b)).

Arp2 and Arp3

Arp2 and Arp3 are both subunits of a seven-member protein complex, called the 'Arp2/3 complex' that is an essential regulator of the actin cytoskeleton. The Arp2/3 complex nucleates formation of new actin filaments in response to activation of intracellular signaling systems. It also cross-links actin filaments into mechanically rigid networks so that, in general, it functions to convert intracellular signals into cytoskeletal

structures. Within the complex, the Arp2 and Arp3 subunits are thought to form a heterodimer with a surface that mimics the fast-growing, barbed end of an actin filament. This surface forms a template to initiate actin filament formation. In the crystal structure of the complex, Arp2 and Arp3 are separated by a large (40 Å) cleft and formation of an actin-like Arp2–Arp3 dimer would require a significant conformational change. This conformational change may require ATP hydrolysis on one of the Arps (**Figure 3(c)**). Binding of ATP to Arp2/3 is required for actin nucleation and neither ADP nor nonhydrolyzable ATP analogs support Arp2/3-dependent actin filament nucleation. Further study is required to understand the connection between ATP hydrolysis and conformational changes on the Arp2/3 complex.

Chromatin-Associated Arps

Several Arps are associated with eukaryotic chromatin and with chromatin-remodeling complexes. In budding yeast, Arp4, Arp5, Arp7, Arp8, and Arp9 are subunits of ATP-dependent chromatin remodeling complexes. Very little is known about the molecular mechanisms of their activity, but presumably adenosine triphosphatase (ATPase)-driven conformational changes in the Arp subunits regulate the overall structure and activity of these complexes. All of these complexes contain two or four Arp subunits so it is possible that they function as heterodimers and that their interaction is regulated in a manner similar to that of the Arp2/3 complex described earlier.

Arp4

Arp4 is involved in chromatin remodeling and transcriptional activation. In budding yeast, Arp4 is a subunit of both the NuA4 histone acetyl-transferase complex and the INO80 chromatin-remodeling complex. The NuA4 complex acetylates histones H4 and H2A. Acetylation increases accessibility of the DNA within the nucleosome and recruits other chromatin remodeling enzymes to the region. Human cells contain a similar histone acetyl-transferase complex, called 'Tip60'. This complex also contains an Arp4-type subunit in addition to at least one monomer of conventional actin. The INO80 complex contains Arp4 as well as Arp5, Arp8, and conventional actin. The precise role of Arp4 in these complexes is unknown but yeast Arp4 mutants exhibit phenotypes similar to mutants missing the catalytic acetylase subunit of NuA4, suggesting that it plays an integral role in the function of the NuA4 complex. Arp4 has also been shown to bind directly to histones. Its ATPase activity has not been well studied but Arp4 may use ATP binding and hydrolysis to regulate the interaction between chromatin-remodeling complexes and DNA-bound histones.

Arp5 and Arp8

Arp5 and Arp8 (along with Arp4 and conventional actin) are members of the INO80 chromatin-remodeling complex. INO80 is a large (2 MDa) protein complex that plays a role in transcription of several important yeast genes including *pho5*, an essential regulator of phosphate metabolism. The total number of yeast genes that require INO80 activity for transcription is not known. Arp8 has been shown to bind directly to histones H3 and H4 so it may be directly involved in moving histones around on the DNA. Arp8 is also required for the incorporation of both

Arp4 and conventional actin into the complex so it may play an important structural or scaffolding role.

Arp7 and Arp9

Arp7 and Arp9 associate tightly to form a heterodimer and dimerization appears to be important to their cellular function. In budding yeast, the Arp7/Arp9 dimer is an essential part of both the Swi/Snf and RSC chromatin-remodeling complexes. Like the INO80 complex, these large complexes drive DNA and histone rearrangements necessary for transcription. Swi/Snf activity is required for transcription of ~5% of yeast genes while RSC activity is more globally important. As with the other chromatin-associated Arps, the precise functions of Arp7 and Arp9 are unknown. Loss of the RSC complex is lethal. The loss of either Arp7 or Arp9 causes severe growth defects *in vivo* but does not significantly impair RSC activity *in vitro*. So *in vivo* the Arp7/Arp9 dimer may act to correctly target or regulate the RSC complex.

Chromatin-associated conventional actin

The large majority of cellular actin is cytoplasmic and generally actin is considered as a cytoskeletal protein whose function is limited to the cytoplasm. In many species, however, chromatin-remodeling complexes contain one or more tightly associated monomers of conventional actin. In addition to Arp4, the NuA4 complex contains a subunit of conventional actin. Also, the yeast INO80 complex and the mammalian Brg- or hBrm-associated factor (BAF) complex (a chromatin-remodeling complex similar to the budding yeast swi/snf) contain tightly associated actin monomers. The role of conventional actin in chromatin structure and remodeling is mysterious. It has been speculated that actin assembly in the nucleus could drive large-scale changes in chromatin architecture in the way that actin assembly in the cytoplasm drives large-scale plasma membrane movements. It is also possible that short actin filaments form an essential scaffold for the assembly and function of chromatin organizing factors.

Arps of unknown function

We know almost nothing about the function of Arp6. In budding yeast Arp6 is localized to the nucleus so it may be part of a chromatin-remodeling complex or it may play a role in determining nuclear architecture.

Glossary

G protein A heterotrimeric protein composed of an α -, β -, and γ -subunit that binds and hydrolyzes guanosine triphosphate (GTP) and transduces signals from outside to the inside of the cell.

Receptor A protein that resides in the plasma membrane and specifically recognizes an extracellular signal and upon binding of this signal, transmits information to the cell interior.

Second messenger A small molecule that is synthesized by a cellular protein and conveys the information within the cell that an extracellular signal has been received.

Signal transduction The process of transmitting information from the outside to the inside of a cell, resulting in a change in cellular behavior.

Adenylyl cyclases are enzymes that synthesize the intracellular second messenger, cyclic adenosine monophosphate (cAMP), which in turn triggers a cascade of biochemical changes that regulate a number of important cellular processes. These cAMP-regulated cellular processes play an important role in the control of a number of metabolic processes including the regulation of blood glucose homeostasis, learning and memory, and cell growth.

The Hormone-Regulated Adenylyl Cyclase System

In order to function and survive, cells must respond to a multitude of signals present in their environment. These include chemical messengers released from local or distant parts of the body (such as circulating hormones and neurotransmitters) and external stimuli (such as light and odorants). Typically, these chemical messengers do not cross the cell membrane, but rather transduce their signal to the interior of the cell utilizing a hand-off mechanism occurring at the plasma membrane. In this process, the stimulus or first messenger acts at the membrane to regulate the activity of an enzyme that synthesizes (or degrades) an intracellular second messenger that can in turn regulate downstream intracellular metabolic enzymes (Figure 1). cAMP, which is synthesized by adenylyl cyclases, was the first of these second messengers identified, and this mechanism has subsequently shown to be utilized as a common biological strategy to regulate cellular behaviors.

Regulation of intracellular cAMP concentrations is principally controlled at the level of its synthesis, through the hormonal regulation of adenylyl cyclase, the enzyme responsible for the conversion of adenosine triphosphate (ATP) into cAMP. The adenylyl cyclase system is comprised of three components: heptahelical G-protein-coupled receptors for a variety of hormones, neurotransmitters, and odorants; heterotrimeric G proteins; and the catalytic entity itself. Nine isoforms of membrane-bound adenylyl cyclases and a single soluble form have been identified in man. The nine-membrane-bound isoforms are subjected to hormonal regulation that is mediated by G proteins of the G_s , G_i subclasses. Most importantly, adenylyl

cyclase isoforms have the ability to integrate the multitude of hormonal inputs relayed by these pathways to ultimately control intracellular cAMP levels.

Discovery

The identification of cAMP resulted from studies aimed at elucidating the biochemical mechanism underlying the breakdown of glycogen in liver cells that is triggered by the hormone glucagon. In his Nobel-prize-winning discoveries, Earl Sutherland demonstrated that the process involved two distinct stages, a binding of the hormone at the membrane that activated adenylyl cyclase and subsequently generated the second messenger cAMP, and the activation within the cell of the downstream enzymatic process. The later discoveries that the receptor and the adenylyl cyclase were two distinct entities, and the subsequent identification of a third component (the intervening heterotrimeric G protein) have provided our modern day model of the hormone-regulated adenylyl cyclase system. Almost three decades following the discovery of cAMP, the genetic material encoding the first adenylyl cyclase was isolated, which further exposed the complexity of this signaling system.

Members of the Family

Our current knowledge of the structure and function of the mammalian adenylyl cyclase family has reached a new understanding following the application of molecular approaches. Ten distinct genes encoding the soluble and membrane-bound adenylyl cyclases have been identified (Table 1). These genes are broadly distributed on different chromosomes throughout the human genome. Further diversity of adenylyl cyclases is provided by alternatively spliced messenger RNAs derived from transcripts of some of the family members.

These 10 genes are differentially expressed in various tissues in mammalian species. All isoforms of adenylyl cyclase appear to be expressed in the brain; however, expression of each isoform is limited to specific regions of the central nervous

Figure 1 Schematic diagram of second messenger systems. The diagram above outlines the progression of cell signaling from the extracellular signal (first messenger) to the generation of intracellular second messengers. The lettered subheadings below outline specific examples of intracellular second messengers, their extracellular signals, and the cellular proteins that mediate the changes in the levels of the second messengers. Arrows indicate the direction of the flow of information.

system. Additionally, some adenylyl cyclase appears to be rather widely distributed in most tissues of the body (e.g., types 4, 6, and 7). All adenylyl cyclases have roughly the same size and contain between 1064 and 1610 amino acid residues. The deduced amino acid sequence of all identified adenylyl cyclase isoforms predicts a complex topology within the membrane (**Figure 2**). The noted exception is the soluble adenylyl cyclase (SAC), which is localized to the intracellular compartment and exhibits regulation quite distinct from the membrane-bound forms. This isoform is more related to an ancestral form found in bacteria than to the other types.

Based on the similarities of their amino acid sequences, and patterns of regulation by G protein pathways, the membrane-bound adenylyl cyclases can be grouped into subfamilies. The first group, comprised of the types 1 and 8, are characterized by their stimulation by calmodulin. The types 2, 4, and 7 adenylyl cyclases form the second group; characteristic of these isoforms is their stimulation by G protein $\beta\gamma$ -subunits. Types 5 and 6, which are the two most related isoforms constitute the last group and are characterized by their inhibition by calcium. The type 9 is the largest and most diverse of the adenylyl cyclase isoforms, and like the type 3 enzyme, does not belong to any of the three groups outlined above.

Table 1 Localization and expression of the adenylyl cyclase gene family

<i>AC isoform</i>	<i>Length (amino acids)</i>	<i>Location (chromosome)</i>	<i>Sites of expression (tissue)</i>
AC1	1135	7	Brain and adrenal medulla
AC2	1090	5	Brain, skeletal muscle, lung, and heart
AC3	1144	2	Olfactory epithelium, and brain
AC4	1064	14	Widely distributed
AC5	1184	3	Heart, brain, kidney, liver, lung, and uterus
AC6	1165	12	Ubiquitous
AC7	1099	16	Ubiquitous (highly expressed in brain)
AC8	1248	8	Brain and lung, (some in testes, adrenal, uterus, and heart)
AC9	1353	16	Brain, skeletal muscle, lung, and heart
SAC	1610	1	Testes

Figure 2 Schematic view of plasma membrane components that participate in the hormone-regulated adenylyl cyclase system. A prototypic adenylyl cyclase is shown. G-protein-coupled receptors that enhance or inhibit adenylyl cyclase activity are shown in green and red, respectively. All receptors of this family have a similar predicted structure and span the plasma membrane seven times. These receptors couple to their corresponding heterotrimeric G proteins (composed of α -, β -, and γ -subunits); G_s (green) and G_i (red) couple to stimulatory and inhibitory receptors, respectively. Adenylyl cyclase (shown in blue) is predicted to span the plasma membrane 12 times, and projects its active site toward the cytoplasmic side of the membrane. The result of extracellular messengers binding to the receptors results in the regulation of the conversion of ATP into cAMP by the enzyme adenylyl cyclase.

Figure 3 Schematic representation of the isoform-specific regulation of adenylyl cyclases by G protein subunits. (a) Regulation of adenylyl cyclases by $G_s\alpha$. Upon activation of stimulatory receptors, the heterotrimeric G protein, G_s undergoes subunit dissociation whereby the $\beta\gamma$ -subunits are released from the α -subunit. The α -subunit subsequently binds to the adenylyl cyclase and increases its catalytic activity, resulting in an increase in intracellular cAMP levels (+). (b) Regulation of adenylyl cyclases by $G_i\alpha$. Upon activation of inhibitory receptors, the heterotrimeric G protein, G_i undergoes subunit dissociation whereby the $\beta\gamma$ -subunits are released from the α -subunit. The α -subunit subsequently binds to the adenylyl cyclase and decreases its catalytic activity, resulting in a decrease in intracellular cAMP levels (-). Specific isoforms of adenylyl cyclase that are responsive to G_i inhibition are noted. (c) Dual regulation of adenylyl cyclases by G-protein $\beta\gamma$ -subunits. $\beta\gamma$ -subunits released from G_i heterotrimers can either positively (+) or negatively (-) regulate adenylyl cyclases. Specific isoforms of adenylyl cyclase that are responsive to these two types of regulation are noted.

Regulation of Adenylyl Cyclase Activity by G Proteins and Calcium

There are multiple classes of heterotrimeric G proteins that regulate adenylyl cyclases, either in a stimulatory (G_s family) or in an inhibitory (G_i family) manner. The two G protein families are normally coupled to distinct receptor subtypes. The $\beta\gamma$ -subunits also regulate adenylyl cyclase activity, but in a manner specific to an adenylyl cyclase isoform. Additionally, calcium ions are very strong modulators of some isoforms of adenylyl cyclase; thus, G proteins that regulate calcium entry through voltage-dependent Ca^{2+} channels may also regulate adenylyl cyclase activity.

Hormonal activation of AC occurs primarily through receptors coupled to the stimulatory G protein G_s . G_s is the most widely distributed activator of all mammalian membrane-bound AC isoforms. All membrane-bound forms of adenylyl cyclases are regulated by G_s through the interaction of adenylyl cyclase with the $G\alpha$ -subunit that is released from the $\beta\gamma$ -subunits upon activation by a hormone-bound stimulating receptor (Figure 3(a)).

Members of the G_i family inhibit adenylyl cyclase activity through the binding of the alpha subunit to the cyclase, but this regulation exhibits selectivity for a subset of adenylyl cyclase isoforms (Figure 3(b)). All three G_i family members (G_{i1} , G_{i2} , and G_{i3}) inhibit types 1, 5, 6, and 8; the remaining cyclase isoforms are insensitive to this inhibitory input. Interestingly, this mode of inhibition is not through direct competition with G_s binding to the cyclase, and a number of experimental approaches demonstrate that $G_{i\alpha}$ exerts its effects at a site, symmetrical to the G_s binding site, and located on the side opposite the cyclase molecule.

As illustrated in Figure 3(c), activation of inhibitory receptors leads to the release of G protein $\beta\gamma$ -subunits which can exert profound regulation of adenylyl cyclase activity. Like

regulation by the G_i α -subunit, this regulation is isoform specific. However, an added complication is that the $\beta\gamma$ -subunits can either activate or inhibit the activity – types 2, 4, and 7 are activated whereas types 1 and 8 are inhibited.

Regulation of adenylyl cyclase activity by calcium is still more complex (Figure 4). At physiological intracellular calcium concentrations the types 3, 5, and 6 adenylyl cyclases are inhibited by calcium. For the types 5 and 6, this appears to be due to a direct effect of calcium on the adenylyl cyclase. Stimulation of adenylyl cyclase activity by calcium has been demonstrated for the types 1 and 8 isoforms, but this form of regulation requires calmodulin, a calcium-binding protein that regulates the activity of many cellular enzymes. Indeed, one of these calmodulin-regulated enzymes is a protein kinase, that mediates the inhibitory effects that were observed for the type 3 adenylyl cyclase.

Physiological Roles of Adenylyl Cyclases

The hormonal activation of adenylyl cyclases and the subsequent regulation of intracellular cAMP impacts on a wide array of cellular processes (Table 2). These roles include diverse processes underlying regulation of blood sugar levels, regulation of heart function, water retention as well as higher brain functions of learning and memory. However, while much is known at the biochemical level regarding the regulation of the many adenylyl cyclase isoforms, the precise physiological roles of each isoform are less well known. A further complication is that each cell of our body expresses more than one isoform of adenylyl cyclase. Nevertheless, investigators have begun to examine the specific roles of each adenylyl cyclase isoform through the use of mouse strains that are genetically altered by the removal of a particular adenylyl cyclase gene from the mouse genome. Such studies emphasize the involvement of

Figure 4 Schematic representation of the isoform-specific regulation of adenylyl cyclases by calcium. Increases in intracellular calcium can regulate the activities of adenylyl cyclases by at least three mechanisms. Calcium can directly bind to and inhibit AC 5 and 6. Calcium bound to calmodulin can bind directly to and activate AC 1 and 8, or can bind and activate a calmodulin-regulated kinase that can subsequently inhibit AC3.

Table 2 Examples of physiological effects mediated by adenylyl cyclases

<i>Extracellular signal (hormone or chemical)</i>	<i>Tissue</i>	<i>Isoform (if known)</i>	<i>Effect</i>
Adrenaline	Heart	AC5 and 6	Increased rate and force of contraction
Adrenaline glucagon	Liver	Unknown	Breakdown of glucagon into glucose
Neurotransmitters (e.g., serotonin and dopamine)	Brain	Many	Learning, memory, and synaptic transmission
Chemical odorants	Olfactory epithelium	AC3	Odorant sensation
Antidiuretic hormone	Kidney	Unknown	Regulation of water retention
Prostaglandin	Arteries	AC3	Inhibition of smooth muscle cell proliferation
Bicarbonate	Testes	SAC	Fertilization (sperm acrosome reaction)

cAMP-signaling pathways in pattern formation of the brain and provide definitive evidence for roles of the types 1 and 8 adenylyl cyclases in higher brain function. Similar approaches have revealed a role for the type 3 cyclase in regulation of smooth muscle proliferation in the aorta and, recently, a role of the type 5 cyclase in heart function.

A number of studies have uncovered both sporadic and inherited mutations in components of the adenylyl cyclase system associated, or in some cases, shown to be causal to certain human diseases. Mutations causing constitutively active receptors resulting in elevated intracellular cAMP levels due to constant stimulation of adenylyl cyclase via G_{sz} have been found in patients with familial male precocious puberty/testotoxicosis (LH receptor), hyperfunctioning thyroid adenomas and nonautoimmune autosomal dominant hyperthyroidism (thyroid-stimulating hormone receptor), and Jansen-type metaphyseal chondrodysplasia (parathyroid hormone receptor). Similarly, diseases associated with constitutively activated G proteins (G_{sz}) were also identified in patients with endocrine tumors, McCune–Albright syndrome, and testotoxicosis. However, to date no mutations associated with these diseases have been found in the adenylyl cyclase component of this system, but these investigations are ongoing. Here again, a major

complication of these studies is the presence of multiple adenylyl cyclase isoforms that are present in each of the cell types.

Glossary

Adipocytes Mammalian cells that store most of the whole body energy reserves in triacylglycerides (TAGs), commonly referred to as fat cells.

Adipocyte triglyceride lipase (ATGL/PNPLA2) An enzyme that catalyzes the rate-limiting step in TAG hydrolysis in adipocytes.

Comparative gene identification-58 (CGI-58) or α/β -hydrolase domain containing 5 (ABHD5)
A protein required to maximally activate ATGL.

Hormone-sensitive lipase (HSL) A hormonally regulated enzyme primarily responsible for catalyzing diacylglyceride hydrolysis within adipocytes.

Lipid droplets (LDs) Organelles with a hydrophobic inner core of neutral lipids, which serve as energy reserves and metabolic precursors.

Lipolysis The degradation of TAGs into free fatty acids and glycerol.

Perilipin 1 (Plin1) The most abundant Plin in adipocytes.

Perilipin protein family Plin proteins that share common amino acid sequence motifs and target LD surfaces.

Introduction

Nature's solution for packaging energy reserves in organisms as diverse as plants and mammals is to sequester energy-rich fatty acids within intracellular neutral lipid storage droplets in the form of triacylglycerides (TAGs) or cholesteryl esters (CEs). The great survival value for this type of packaging is attributed to the high density of energy in fatty acids and the relatively low requirement of water for their storage. If humans were to carry the energy equivalent of fat as carbohydrate, the additional required water would render them immobile. Typically, intracellular neutral lipid storage droplets are coated with specific targeting classes of proteins; proteins involved in lipid metabolism may also be found in tight association. We discuss the functional interactions among these protein and their cooperative roles in the activation and suppression of lipolysis, TAG hydrolysis, in mammalian adipocytes.

Lipid Droplets

The first reports describing the existence of lipid droplets (LDs) within cells dates to the invention of the light microscope. Such LDs were long considered simple reservoirs of energy, and garnered little attention. Studies of proteins binding to lipids in humans initiated with the discovery of lipoproteins, circulating lipids in plasma. Later, oil bodies, a terminology used in plants, were described together with their coat proteins, the oleosins. The oleosins protect the deposited lipids during desiccation of plant seeds and tapeta. In animal cells, the LD coat proteins help sequester lipids from the cytosol and regulate their access to lipases.

Intracellular LD-Binding Proteins of Animal Cells

The filament protein Vimentin was the first protein found to associate closely with intracellular LDs in animal cells. Soon thereafter, Perilipin was identified at the LD surface in rat adipocytes. Perilipin has no obvious sequence relationship to vimentin or the oleosins, but is closely related to other animal proteins, which were subsequently found to also localize with intracellular LDs (Figure 1(a), Table 1). Based upon the sequence similarities among these proteins, their shared subcellular localization properties, their similar gene structure organizations, and the multiple names attributed to several of these, a universal nomenclature has been adopted for this gene family, with Perilipin/Plin chosen as the root name and symbol (Table 1). Perilipin is now termed perilipin 1, Plin1.

Genes that encode species-related proteins have also been identified in evolutionary diverse organisms, including *Drosophila melanogaster* and *Dictyostelium discoideum* (Figure 1(a)). These genes are related to the mammalian counterparts not only in their protein-coding sequences, but also in their overall genomic structural organizations, indicating that these genes derive from a gene family of ancient origin. Similar to the mammalian Plins, the *Drosophila* and *Dictyostelium* proteins localize to LDs endogenously or when expressed in mammalian cells. All of these proteins are presumed to share specific structural motifs that determine their unique intracellular LD targeting ability, but the exact nature of this motif is still to be experimentally determined.

Perilipin 1, the Major Adipocyte Perilipin

The most extensively studied perilipin is perilipin 1, Plin1. *Plin1* is a single-copy gene in mice and humans that encodes multiple messenger RNAs (mRNAs) and protein forms (Figure 1(b)). The *Plin1a*, *b*, *c*, *d* mRNAs encode proteins with identical

[†]Deceased.

amino-termini, but distinct carboxyl-termini. All of the Plin1 proteins localize to the surface of neutral lipid deposits (Figure 2), but it is not clear if Plin1 binds at the surface or, like oleosins, is embedded within the phospholipid monolayer, which forms the boundary between the aqueous cytosol and the hydrophobic inner lipid core of the droplet.

Figure 1 (a) Schematic of the major Plin family members. There are five Plin family members in mice and humans, Plins 1–5; alternative names are indicated. The PAT domain name derives from the founding members of the family, Perilipin, ADRP, and TIP47. Only the major Plin1 variant is shown (see (b)). Related lipid storage droplet (LSD) proteins have been identified in *Drosophila*, *Dictyostelium*, and other species. Red boxes indicate the N-terminal PAT domain shared by all members of the Plin family; in Plin4, this region is highly diverged. Blue boxes indicate the 11-mer repeat region also shared by members of the family; in Plin4, this region is more extended. (b) Schematic of Perilipin 1 isoforms and PKA phosphorylation sites. *Perilipin 1* (*Plin1*) is a single-copy gene that encodes multiple mRNAs as the result of differential splicing and poly(A) addition sites. The four Plin1 proteins are diagramed and the sites for phosphorylation by PKA indicated. Red boxes indicate the N-terminal PAT domain shared by all members of the Plin family. Blue boxes indicate the 11-mer repeat region also shared by members of the Plin family. Green boxes indicate regions unique to each Plin1 protein isoform.

Plin1 is preferentially expressed in adipocytes and steroidogenic cells. Only Plin1a and b are expressed in adipocytes, with Plin1a being more abundant. Plin1c and Plin1d are exclusively expressed in steroidogenic cells. Both Plin1a and 1b are hyperphosphorylated upon elevation of cyclic adenosine monophosphate (cAMP) during lipolytic stimulation of adipocytes. Plin1a has six consensus protein kinase A (PKA) phosphorylation sites (Figure 1(b)); the three carboxyl-terminal sites are absent from Plin1b. It is not known if all of the PKA sites in Plin1 are phosphorylated or if phosphorylation occurs in a specific order. As lipolysis in adipocytes is activated by a PKA-mediated process, and given the specific association of Plin1 with adipocyte LDs, it was early predicted that Plin1 would play an essential role in the regulation of adipocyte lipolysis. Functional analyses in cell culture systems and in mice lacking expression of all Plin1 forms confirm this early speculation.

The Dual Nature for Plin1 Regulation of Lipolysis in Adipocytes

Adipocytes store most of the whole body energy depots in TAG-containing LDs. To maintain these energy reserves, yet allow their release under restricted conditions, lipolysis in adipocytes is subject to complex regulation. Depending on its PKA-dependent phosphorylation state, Plin1 exhibits two opposing functions in the regulation of lipolysis in adipocytes. Nonphosphorylated Plin1 appears to shield TAGs within LDs from hydrolysis by lipases. By contrast, when phosphorylated by PKA, Plin1 facilitates lipase-mediated TAG hydrolysis. The protective function of Plin1 is best illustrated by the *Plin1*^{−/−} mouse that exhibits a ~70% decrease in adipose tissue without a change in gross animal weight or in caloric intake. This reduction in adipose tissue mass is attributed to the constitutively elevated rate of basal lipolysis in adipocytes lacking Plin1. Thus, Plin1 is essential for mice to retain their TAG depots. These mice also reveal a critical role for Plin1 in stimulated lipolysis. In the absence of Plin1, adipocytes fail to respond maximally to lipolytic stimuli. In comparison to *Plin1*^{+/+} wild-type (WT) cells, PKA-activated *Plin1*^{−/−} adipocytes have attenuated lipolysis. This dual nature for Plin1 function has been mechanistically confirmed by expressing WT and phospho-site mutant forms of Plin1a and Plin1b in fibroblastic cells which do not normally express Plin1.

Dissecting the Adipocyte Lipolysis Model

For many years, the prevailing model for adipocyte lipolysis was that hormone-sensitive lipase (HSL) was the rate-limiting

Table 1 The human/mouse Perilipin (Plin) protein family

Approved human symbol	Approved name	Previous aliases	Primary tissue protein expression
PLIN1	Perilipin 1	Perilipin	Adipose, steroidogenic cells
PLIN2	Perilipin 2	ADRP, ADFP, adipophilin	Ubiquitous enriched in liver, muscle, fibroblasts, not adipose
PLIN3	Perilipin 3	TIP47, pp17	Ubiquitous
PLIN4	Perilipin 4	S3-12	Adipose, heart, glycolytic muscle
PLIN5	Perilipin 5	LSDP5, PAT1, OXPAT, MLDP	Heart, oxidative muscle, brown fat

Figure 2 Co-localization of Plin1 with lipid droplets of adipocytes. Isolated rat adipocytes were stained for neutral lipids with Nile red and immunostained for Perilipin1 protein with α -Plin1. Plin1 localizes to the surface of intracellular LDs.

Figure 3 Stimulated migration of HSL from the cytosol to lipid droplet surfaces requires Perilipin 1. Adipocytes were isolated from *Plin1*^{+/+} or *Plin1*^{-/-} mice. Cells were maintained in a basal state or lipolytically stimulated with isoproterenol. Subcellular localization of hormone-sensitive lipase (HSL) was determined by immunostaining. HSL is cytosolic in basal cells. Upon stimulation, HSL redistributes to the surface of LDs in adipocytes of *Plin1*^{+/+} mice but not of *Plin1*^{-/-} mice.

enzyme and that lipolytic rates *in vivo* were regulated exclusively by the PKA-dependent enzymatic activation of HSL. However, this mechanism was questioned because phosphorylation of HSL *in vitro* elicits only a doubling of lipase activity, whereas activation of cellular PKA *in vivo* increases lipolysis 50–100-fold. Further, whereas HSL is localized in the cytosol of quiescent adipocytes, the enzyme is absent in the cytosol of homogenates of stimulated cells, but is associated with LDs (Figure 3). It was further demonstrated that PKA activation led to phosphorylation-dependent translocation of HSL from the cytosol to the surface of LDs.

An important breakthrough in the understanding of HSL translocation came from studies of adipocytes isolated from *Plin1*^{-/-} animals. In the absence of Plin1, HSL cannot translocate from the cytosol to LD surfaces (Figure 3). This finding established HSL translocation, and not phosphorylation *per se*, as a key reaction for stimulated lipolysis in adipocytes and revealed the central role of Plin1 in this process. Translocation

has been reconstituted in fibroblast cells expressing WT and mutant forms of Plin1 and HSL. PKA-dependent phosphorylation of WT HSL and WT Plin1 mediates the translocation process; phospho-HSL does not translocate efficiently in the absence of Plin1 or in the presence of Plin1 variants that cannot be phosphorylated. Similarly, nonphosphorylated HSL does not translocate to LDs even in the presence of phospho-Plin1. This model of translocation of lipases from the cytosol to the LD surface upon PKA activation forms the basis for subsequent work and identification of additional regulatory components in adipocyte lipolysis.

The Current Adipose Lipolysis Model

Based on the above model (see Figure 3), mice lacking HSL posed a surprising phenotype. Instead of having a presumed increase in adipocyte TAG levels, adipocytes from mice lacking HSL were smaller, with less TAG but increased diacylglyceride (DAG) in comparison to WT controls. Although HSL has broad substrate specificity and is capable of hydrolyzing TAG, DAG, monoacylglyceride (MAG), CE, and retinyl ester, TAG is the least favorable substrate. Subsequently, another lipase, adipose triglyceride lipase (ATGL), was identified in adipocytes (and other cells) that exhibited substantially higher substrate specificity for TAG. Loss of ATGL reduced TAG hydrolysis in adipocytes and promoted abnormal accumulation of TAG in many other cells. Indeed, ATGL is a widely expressed enzyme that is the more critical for rate-limiting regulation of lipolysis in multiple tissues. Maximal activity of ATGL requires specific interaction with the α/β -hydrolase domain containing protein CGI-58/ABDH5.

The significance of ATGL and CGI-58 in lipid metabolism is underscored by recent observations that autosomal recessive mutations in either human gene are causative for neutral lipid storage diseases. CGI-58/ABDH5 deficiency in humans is the basis of Chanarin–Dorfman syndrome (CDS), characterized by systemic accumulation of TAG, hepatic steatosis, and ichthyosis. Mutations in ATGL/PNPLA2 are associated with NLSMD, a neutral lipid storage disease with myopathy, and a distinct pattern of TAG accumulation compared with that of CDS. Although CGI-58 is a definitive positive regulator of ATGL, these phenotypic differences suggest that the actions of CGI-58 may not be limited to ATGL and that CGI-58 may regulate lipolytic activity in tissues more broadly than does ATGL. In addition, neither disease is characterized by gross obesity, indicating a central role for HSL, in addition to ATGL, in the regulation of fat mobilization in adipocytes. It is also likely that ATGL activity is subject to negative regulation and recent data implicate G₀/G₁ Switch Gene 2 (G0S2) as a potential inhibitory molecule that can suppress ATGL lipase activity.

Clearly, the activity of the lipolytic enzymes and adipose lipolysis is tightly regulated. There are multiple regulatory cellular inputs, with PKA-mediated signaling being a highly significant pathway. Adipocytes sense body energy reserves in response to circulating hormones. Some act directly on G-protein-coupled receptors to suppress or stimulate adenylyl cyclase activity, with a consequent effect on downstream cAMP production and activity of PKA.

The current model for adipose PKA-mediated lipolysis is depicted in **Figure 4**. In quiescent cells adenylyl cyclase is functionally inhibited (see **Figure 4(a)**); cAMP levels are low, PKA is minimally active, and Plin1 is unphosphorylated. Under these conditions, Plin1 serves as a functional barrier for HSL and ATGL to access TAGs within the inner core of the intracellular LDs in adipocytes. CGI-58 is bound to the LD surface, in complex with the carboxyl-terminal region of unphosphorylated Plin1, which may sequester CGI-58 from interaction with ATGL.

Upon hormonal stimulation and adenylyl cyclase activation (see **Figure 4(b)**), cAMP levels rise, leading to the activation of PKA and the phosphorylation of both Plin1 and HSL. Phosphorylation of Plin1 facilitates binding of HSL to the LD surface. In addition, phosphorylation of HSL by PKA is also required for translocation of HSL from the cytosol to the LDs.

Although phosphorylated Plin1 may serve as a docking site for phosphorylated HSL, this is not fully clarified. Unphosphorylated Plin1 may sterically restrict access of HSL and other lipases from LD surfaces. Phosphorylation of Plin1 also regulates ATGL. In quiescent cells, unphosphorylated Plin1 is complexed with CGI-58 at the LD surface, but phosphorylation of Plin1 is coordinated with the dissociation of CGI-58. This renders CGI-58 accessible for interaction with and activation of ATGL. Released CGI-58 may bind to ATGL in the cytosol and the activated complex may then bind LDs; alternatively, released CGI-58 may remain bound to the LD surface and recruit ATGL to the LD. There are data to support both mechanisms.

In summary, Plin1 serves as a functional barrier to lipase access to TAGs in quiescent cells, but PKA stimulation initiates a cascade of events that ultimately activate lipolysis. Both Plin1

Figure 4 Model for PKA-mediated lipolytic activation in adipocytes. (a) Quiescent cells: adenylyl cyclase (AC) is inactive through coupling to inhibitory $G\alpha$ subunits. Here, the adenosine analog phenylisopropyladenosine (Pia) activates adenosine type 1 receptors, which promotes formation of the $G\alpha i$ -GTP inhibitory complex. Intracellular cAMP levels are suppressed and protein kinase A (PKA) is inactive. At the LD surface, Plin1 (Perlipin 1) interacts with CGI-58; hormone-sensitive lipase (HSL) and adipose triacylglyceride lipase (ATGL) are primarily cytosolic. (b) Activated cells: adenylyl cyclase (AC) is activated through interaction with stimulatory $G\alpha$ subunits. Here, the β_2 -adrenergic receptor agonist isoproterenol (Iso) promotes formation of the $G\alpha s$ -GTP stimulatory complex. Intracellular cAMP levels rise and protein kinase A (PKA) is activated. In turn, PKA phosphorylates both Plin1 and HSL. At the LD surface, phospho-Plin1 recruits phospho-HSL and CGI-58 is released. CGI-58 couples with and activates ATGL at the LD surface. Accordingly, triacylglycerides become hydrolyzed to free fatty acids (FFA) and glycerol and are secreted.

and HSL are phosphorylated by PKA; functionally activated ATGL and HSL translocate to LD surfaces, and lipolytic rates are stimulated 50–100-fold above basal levels. Thus, in *Plin1*^{-/-} adipocytes, basal rates of lipolysis are elevated due to loss of barrier function, but activated lipolysis is attenuated due to loss of lipase recruitment.

The Function of Other Plins in the Regulation of Lipid Metabolism in Various Tissues and Organisms

The shared structural organization of the Plins suggests that all Plin family members may regulate LD function. Each of the various mammalian Plins have distinct expression patterns and are likely to regulate lipolysis and, potentially other processes, in a distinct manner. Plin2, although usually absent in differentiated adipocytes, is the predominant protein found at LD surfaces of *Plin1*^{-/-} adipocytes. Certainly, the appearance of Plin2, in addition to the loss of Plin1, may contribute to the lipolytic defects in these cells.

A general role for the Plins in lipid metabolism is emerging. Plins 2, 3, and 5, can partially protect TAG from lipases; in their absence, fatty acids are released at an elevated level. The increased release of fatty acids from LDs interferes with cellular insulin signaling and can induce insulin resistance in cultured liver cells. Thus, the Plins may sequester TAG from lipase action and help maintain insulin sensitivity. Recent data in *Drosophila* extend these observations. *Drosophila* lacking one of their two Plin-related proteins exhibit a lean phenotype, while overexpression promotes an increase in TAG stores, phenotypes consistent with a general protective function for the Plins in lipid storage.

Glossary

Clone/mitotic clonal expansion A clone is a group of cells that has arisen from a single cell and which have the identical genome.

Commitment The process that mesenchymal stem cells (MSCs) undergo to give rise to cells of a single lineage.

Hyperplasia An increase in cell number.

Hypertrophy An increase in cell size/content.

Mesenchymal stem cells (MSCs) Pluripotent cells arising from the embryonic mesoderm that have the capacity to commit/differentiate into cells of the adipocyte, muscle, cartilage, or bone lineages.

Introduction

Adipogenesis is the process by which fat-laden cells, that is, adipocytes, develop and accumulate as adipose tissue at various sites in the body, both as subcutaneous fat and as depots. The major roles of adipocytes are to store energy as fat during periods when energy intake exceeds expenditure and to mobilize this stored fuel when energy expenditure exceeds intake. Adipocytes arise both during late embryonic development and in the mature animal under conditions that promote obesity. Obesity – the excessive accumulation of body fat – is a consequence of persistent energy intake that exceeds energy expenditure. This condition gives rise both to hyperplasia (an increase in number) and to hypertrophy (an increase in size) of tissue adipocytes (Figure 1). An increasingly sedentary lifestyle coupled with an energy-rich diet has contributed to a high frequency of obesity and its attendant health problems, including type 2 diabetes.

Adipocytes also function in the control of metabolism through the secretion of paracrine and endocrine hormones/factors (e.g., leptin and adiponectin) that affect feeding behavior, metabolism, insulin sensitivity and secretion, and reproductive and immune functions. As the largest energy reserve in the body, adipose tissue has a major impact on energy flux, plasma lipid levels, and rates of glucose uptake. An understanding of the development program and its regulation is required to comprehend the roles of adipocytes.

Origin of Adipocytes

Adipocytes are derived from a pluripotent stem cell population that has the capacity both to self-renew and to differentiate into various cell types. While the fertilized egg is totipotent and can give rise to all adult cell types, mesenchymal stem cells (MSCs) are more restricted in their developmental potential, that is, they are pluripotent. Such cells can commit and differentiate into a limited number of cell types including adipocytes, osteocytes, chondrocytes, and myocytes. MSCs are found in adipose tissue, bone marrow, and muscle tissue. Recent evidence indicates that MSCs enter the bloodstream, presumably to populate and replenish this population in these sites. MSCs allow the replacement of missing or damaged cells following injury and, in expanding adipose tissue, provide a

reservoir of adipocyte progenitors that can proliferate and differentiate into mature adipocytes.

MSCs from adipose tissue can readily be isolated and this population expanded, making them an attractive source of MSCs for therapeutic use. Furthermore, recent evidence indicates that adult stem cells may have greater developmental plasticity than previously thought. It has been reported that MSCs are capable of committing and differentiating into non-mesodermal cell types; however, this transdifferentiation remains controversial. A greater understanding of the genetic mechanisms that orchestrate development may allow recapitulation of developmental processes *ex vivo* by directing totipotent or pluripotent stem cells to adopt specific fates for cell-based therapies. In addition, a better understanding of the mechanisms that regulate differentiation of terminally differentiated cell types, such as osteoblasts or adipocytes, may yield therapeutic interventions in pathological conditions such as osteoporosis or obesity.

The Adipocyte Development Program

Cell Culture and *In Vivo* Models

Much of what is known concerning adipocyte development has been derived from studies with cell-culture models. Two basic model systems have been employed: (1) multipotent stem cell lines that have not yet undergone commitment to the adipocyte lineage, and (2) preadipocyte cell lines that have undergone commitment to the adipocyte lineage and can be induced to terminally differentiate into adipocytes in cell culture (or when implanted subcutaneously into athymic mice). Pluripotent MSCs can be induced to undergo commitment in cell culture into several distinct cell lineages including the adipoblasts, myoblasts, osteoblasts, and chondroblasts. Once committed, preadipocytes can be induced to differentiate into adipocytes, but not into other cell types. For convenience, the following discussion of adipogenesis will be divided into two sections, commitment and differentiation.

Commitment

The MSC cell line most widely used to study commitment to the adipocyte lineage is the C3H10T1/2 line (referred to as the 10T1/2 line). This cell line was isolated from 14- to 17-day C3H mouse embryos and displays fibroblastic morphology

in culture. These cells are functionally similar to MSCs of mesodermal origin since they have the capacity (upon brief exposure to 4-azacytidine, a DNA methyl transferase inhibitor) to convert into a limited number of cell types that (when induced to differentiate) display the morphological and biochemical characteristics of adipocytes, myocytes, chondrocytes, or osteocytes. The conversion to each of these cell types is heritable as clonal lines can be isolated that retain these specific phenotypes without further treatment with 4-azacytidine. It is believed that this phenotypic alteration results from hypomethylation of a small number (one or two) of regulatory genes involved in the commitment process. By following this procedure, MyoD – a transcription factor that converts the 10T1/2 cells to myoblasts – was discovered. Use of this strategy with uncommitted 10T1/2 stem cells gave rise to several committed preadipocyte cell lines that have been extensively studied. Unlike the 10T1/2 progenitor line, these lines, for example, an A33 preadipocyte line derived from 10T1/2 cells treated with 4-azacytidine, undergo differentiation into adipocytes when subjected to the adipocyte differentiation protocol (see below).

The 10T1/2 cells also respond to treatment with bone morphogenetic proteins (BMPs), members of the transforming growth factor- β superfamily. BMPs are known morphogens that control embryonic patterning, most notably of the mesoderm from which MSCs are derived. BMP2 and BMP4 have been shown to play a role in the control of MSC commitment, promoting adipose, cartilage, or bone lineages, depending on culture conditions. Thus, treatment of 10T1/2 cells with BMP4 induces virtually complete commitment and subsequent differentiation to the adipocyte lineage. Evidence indicates that BMP4 is a morphogen that acts in the adipocyte commitment pathway. An outline of the steps thought to be involved in commitment of MSCs to the adipocyte lineage is shown in Figure 2.

The Wnt pathway

Wnts have been shown to act upstream of BMP4. They are secreted glycoproteins that serve as ligands for members of the frizzled receptor family. Wnts appear to function at two points in the adipogenic pathway – both in the commitment

Figure 1 Adipocyte hyperplasia and hypertrophy are responsible for the increased adiposity/obesity that occurs when energy intake exceeds expenditure.

and differentiation phases. Active Wnt signaling is known to suppress the activity of GSK3 β , a protein kinase in a complex of several other proteins (axin, APC, and β -catenin), by blocking phosphorylation of the β -catenin. This action stabilizes β -catenin and facilitates its translocation into the nucleus where it acts as co-activator for several transcription factors of lymphoid-enhancing factor/T-cell factor (Lef/Tcf) family. During commitment, Wnt signaling is activated and initiates the pathway illustrated in Figure 2, which includes activating the expression of BMP4.

In contrast, active Wnt signaling suppresses differentiation. Thus, for differentiation to occur Wnt signaling is inactivated. In the absence of Wnt signaling, GSK3 β is active leading to the phosphorylation of β -catenin targeting it for destruction by the proteasomal system. Thus, inactivation of Wnt is permissive for adipogenic differentiation. Since active Wnt signaling promotes the activation of β -catenin and blocks expression of C/EBP α and PPAR γ , Wnt signaling must be inactivated for differentiation to proceed. It should be noted that active Wnt promotes osteogenesis and myogenesis – a branch point in development from mesodermal pluripotent MSCs (see Figure 2).

Comparison of differential gene expression patterns between 10T1/2 stem cells and A33 preadipocytes by gene chip analysis indicates that activation of a small set of genes during the 10T1/2 cells-to-preadipocyte transition is responsible for acquisition of the preadipocyte phenotype. Together, these observations indicate that Wnt signaling plays a dual activating role early in adipocyte development and an inhibitory role later during

Figure 2 Intermediates in the commitment pathway by which mesenchymal stem cells (MSCs) undergo conversion into the preadipocytes. The probable role of Wnt in stem cell commitment to the adipocyte lineage is illustrated. It is visualized that R-spondins activate the Wnt/ β -catenin signaling cascade that leads to expression of BMP-4. BMP-4, acting via Smad signaling and an as-yet unidentified downstream intermediary (possibly CREB), induces the expression of C/EBP β , transcriptional activator of C/EBP α and PPAR γ . C/EBP α and PPAR γ act as pleiotropic activators of genes whose expression defines the terminally differentiated adipocyte phenotype.

the terminal differentiation phase. Thus, Wnt activity must be suppressed during the differentiation phase of adipogenesis.

Differentiation

Research with established preadipocyte cell lines has provided much of our knowledge concerning adipocyte differentiation. These homogeneous cell populations can be induced in cell culture to synchronously enter the stably differentiated state. The subcutaneous implantation of 3T3-F442A preadipocytes into athymic mice resulted in the development of an adipose depot that is indistinguishable from endogenous adipose tissue. Thus, this use of the cells provides a test for authenticity of findings made in cell culture. The mouse 3T3-L1 and 3T3-F442A lines have been the best-characterized preadipocyte cell lines. These lines were selected from disaggregated mouse embryos for their ability to accumulate cytoplasmic fat and represent faithful models of preadipocyte differentiation process *in vivo*.

Induction of differentiation

The protocol (referred to as MDI) most often used to induce adipocyte differentiation is to treat preadipocytes with a combination of cyclic adenosine monophosphate (cAMP) (or an agent such as methylisobutylxanthine that increases the level of cellular cAMP) and a glucocorticoid (or dexamethasone, a synthetic glucocorticoid mimic), and a high concentration of insulin (as an insulin-like growth factor 1 (IGF-1) mimic) in the presence of fetal bovine serum (FBS). Prior to differentiation, preadipocyte cell lines have a fibroblastic morphology similar to that of preadipose cells in the stroma of adipose tissue. Upon induction of differentiation, the cells lose their fibroblastic character, assume a rounded-up appearance, and acquire the morphological and biochemical characteristics of adipocytes.

Mitotic clonal expansion

In cell culture, the induced preadipocytes become cell-density inhibited and arrest at the G0/G1 cell-cycle boundary. Growth arrest is a prerequisite for preadipocyte differentiation. The growth-arrested cells then synchronously reenter the cell cycle, undergo two to three rounds of mitosis (mitotic clonal expansion), exit the cell cycle, and terminally differentiate. It is believed that DNA replication and the associated changes in chromatin structure that occur during the mitotic clonal expansion process increase the accessibility of *cis*-elements to transacting (transcription) factors, which activate or de-repress transcription of numerous adipocyte gene(s) that produce the adipocyte phenotype.

Terminal differentiation

As the cells complete clonal expansion, they enter a unique growth-arrested stage of the cell cycle, that is, GD, which is permissive for subsequent differentiation. With 3T3-L1 preadipocytes, this process is characterized by changes in expression of cyclin-dependent kinase inhibitors p18, p21, and p27. Even after differentiation has been initiated, the preadipocytes retain the ability to dedifferentiate and reenter mitosis. However, once the cells have exited GD, they become committed to terminal differentiation. Terminal differentiation is maintained, at least in part, through the expression of C/EBP α and PPAR γ . C/EBP α and PPAR γ act synergistically to activate transcription of genes that produce the adipocyte phenotype (Figure 3). The promoter of the C/EBP α gene possesses a C/EBP regulatory element to which C/EBP α can bind and thereby autoactivate its expression and maintain the differentiated state. C/EBP α also has anti-mitotic activity; its over-expression leads to cell cycle arrest, which terminates mitotic clonal expansion. This anti-mitotic activity is through direct interaction with the cyclin-dependent kinases, cdk2 and cdk4. Like

Figure 3 Transcription cascade initiated by C/EBP β , which leads to the expression of the adipogenic genes. C/EBP, CCAAT/enhancer binding protein; PPAR, peroxisome proliferator-activated receptor; 422/aP2, adipocyte-specific fatty acid binding protein; SCD1, stearoyl-CoA desaturase; GLUT4, the insulin-responsive glucose transporter; Ob, gene that encodes leptin.

C/EBP α , PPAR γ has been observed to induce growth arrest in certain cells.

Transcriptional control

After treating 3T3-L1 preadipocytes with a cocktail of differentiation inducers (i.e., MDI, see above), the cells synchronously reenter the cell cycle and begin to express a cascade of transcription factors that ultimately produce the adipocyte phenotype. The sequence of events in this transcriptional cascade is summarized in **Figure 4**. It should be noted that these events were identified primarily in studies with 3T3-L1 and -F442A cells, which have the advantage of proceeding through the entire differentiation program in a synchronous manner, allowing a clear delineation of each step. The transcription factors are listed below in their order of appearance/function in the differentiation program.

cAMP regulatory element binding protein

cAMP activates protein kinase A, which, in turn, rapidly (≤ 5 min) phosphorylates/activates the nuclear transcription factor cAMP regulatory element binding protein (CREB). One of the preadipocyte differentiation inducers, that is, cAMP, acts rapidly in the nucleus to phosphorylate/activate CREB. Activated CREB then binds at two sites in the proximal promoter of C/EBP β gene, thereby triggering its expression. This event triggers the transcriptional cascade that initiates differentiation.

C/EBP β

C/EBP β is an early transcriptional activator of preadipocyte differentiation and is expressed within 4 h of induction of differentiation. Although C/EBP β is expressed immediately (≤ 20 min) after induction of differentiation, it lacks DNA-binding activity, which is acquired much later in the program. Acquisition of DNA binding occurs at ~ 16 h induction, coincident with entry of the cells into the S-phase at the onset of

mitotic clonal expansion. Concomitant with acquisition of DNA-binding activity, C/EBP β becomes localized to centromeres through C/EBP consensus binding sites in centromeric satellite DNA. As indicated above, the transcriptional activation of C/EBP β is regulated by CREB. The C/EBP β gene possesses two CREB-like *cis* regulatory binding sites in its proximal promoter that are necessary for transcriptional activation. The phosphorylation/activation of CREB is closely correlated with the expression of C/EBP β .

Phosphorylation is an important posttranslational modification of C/EBP β that leads to the acquisition of DNA-binding function as preadipocytes traverse to the G1-S checkpoint at the onset of mitotic clonal expansion. C/EBP β is phosphorylated sequentially, first by mitogen-activated protein (MAP) kinase and then much later by GSK3 β . Phosphorylation on Thr188 by MAP kinase occurs within 4 h of induction of differentiation and is required for mitotic clonal expansion; C/EBP β DNA-binding activity and terminal differentiation require additional phosphorylations on Thr179 and Ser184. Phosphorylation at the latter sites by GSK3 β occurs between ~ 16 h after induction. Hyperphosphorylation of C/EBP β at these three sites activates its DNA-binding activity, and although the mechanism by which this occurs is not understood, it is likely that a phosphorylation-induced conformational change is involved.

C/EBP homologous protein

C/EBP homologous protein (CHOP-10) is a member of the C/EBP family that exerts a suppressive effect early in the differentiation program. CHOP-10 is expressed by growth-arrested preadipocytes, but is downregulated when C/EBP β acquires DNA-binding activity. Thus, during preadipocyte differentiation, CHOP-10 heterodimerizes with C/EBP β and prevents acquisition of DNA binding to C/EBP regulatory elements. It appears that the interaction of CHOP-10 with C/EBP β provides a fail-safe mechanism that prevents the acquisition of

Figure 4 Key events in the adipocyte differentiation pathway. P, phosphoryl group; C/EBP, CCAAT/enhancer binding protein; CREB, cAMP regulatory element binding protein; GSK-3 β , glycogen synthase kinase-3 β ; MAPK, mitogen-activated protein kinase; PPAR, peroxisome proliferator-activated receptor; SREBP, sterol regulatory element binding protein-1c; G1 and S, G1- and S-phases of the cell cycle, respectively.

DNA-binding activity by C/EBP β until preadipocytes have entered mitotic clonal expansion.

C/EBP α

C/EBP α is a pleiotropic transcriptional activator of adipocyte-specific genes. Upon acquisition of DNA-binding activity, C/EBP β binds to the proximal promoter and activates the expression of C/EBP α . The promoters of numerous adipocyte genes possess C/EBP regulatory consensus sequences that support transactivation by C/EBP α . Why is there redundancy in the expression of the C/EBP gene family (notably C/EBP β and C/EBP α) during adipogenesis? This may be because C/EBP α has anti-mitotic activity. Thus, the expression of C/EBP α early during adipogenesis prevents preadipocytes from entering mitotic clonal expansion, a requirement for subsequent differentiation. C/EBP α and PPAR γ (see below) are coordinately expressed late in the differentiation program and, together, these transcription factors activate the coordinate expression of the family of genes that give rise to the adipocyte phenotype.

Peroxisome proliferator-activated receptor- γ

Peroxisome proliferator-activated receptor- γ (PPAR γ) is a member of the nuclear hormone receptor family, many of which are activated by ligands that control their activity. PPAR γ is a central regulator in adipogenesis. Like C/EBP α , PPAR γ is responsible for activating a number of genes involved in fatty acid metabolism. C/EBP α and PPAR γ are expressed coordinately during adipocyte differentiation and act together to activate the expression of most of the genes that encode proteins that give rise to the adipocyte phenotype.

Sterol regulatory binding protein

Sterol regulatory binding proteins (SREBPs) are transcription factors that regulate the transcription of numerous genes of cholesterol and fatty acid metabolism (Horton et al., 2002). Of the three members of the SREBP family, only SREBP-1c activates transcription of genes required for fatty acid synthesis, which are required for acquisition of the adipocyte phenotype. What triggers the expression/activation of SREBP-1c during the preadipocyte differentiation program is uncertain; however, it is known that insulin (or IGF1) – one of the differentiation inducers – activates its expression.

Overview

An encapsulation of the adipocyte differentiation pathway is shown in **Figure 4**. The differentiation process is initiated by the rapid phosphorylation of CREB, which activates the expression of C/EBP β via cAMP-responsive regulatory elements within the proximal promoter of the C/EBP β gene. At this point, C/EBP β lacks DNA-binding activity. However, after a lengthy lag period and reentry of the cell cycle C/EBP β undergoes phosphorylation by MAP kinase and later by GSK-3 β . This dual phosphorylation provokes acquisition of DNA-binding activity by C/EBP β , which allows C/EBP β to bind to and transcriptionally activate the genes encoding two key adipogenic transcription factors, that is, C/EBP α and PPAR γ . The coordinate expression of C/EBP α and PPAR γ then acts together to activate the expression of a large group of adipocyte genes. These transcription factors, along with SREBP-1c, activate the production of and maintain the adipocyte phenotype as illustrated in **Figure 4**.

Glossary

Agonist Compound that binds to a receptor and activates it, thus causing a biological response.

Antagonist Compound that binds to a receptor but does not activate it. It can block or inhibit the activation caused by an agonist.

Desensitization Decrease in response of a tissue to a neurotransmitter or agonist drug following repeated administration.

Downregulation Decrease in the number or density of receptor-binding sites following chronic agonist treatment.

Partial agonist Agonist that has less than full efficacy in activating its receptor.

Polymorphism Variability in DNA sequence that occurs with an allele frequency of greater than 1% in the population.

Adrenergic receptors (adrenoceptors) mediate the central and peripheral actions of the neurotransmitter norepinephrine (noradrenaline) and the hormone epinephrine (adrenaline); they are widely distributed throughout the body. There are three major adrenergic receptor types: alpha-1, alpha-2, and beta. Each of these three receptor types is further divided into three subtypes. Adrenergic receptors are seven transmembrane receptors, which consist of a single polypeptide chain with seven hydrophobic regions that form alpha helical structures that span or transverse the membrane. Because the mechanism of action of adrenergic receptors includes the activation of guanine nucleotide regulatory binding proteins (G proteins), they are also called G-protein-coupled receptors.

Epinephrine and Norepinephrine

Norepinephrine (noradrenaline) is a neurotransmitter in both the peripheral and central nervous systems. Epinephrine (adrenaline) is a hormone released from the adrenal gland. Norepinephrine and epinephrine are catecholamines, because they have both the catechol moiety (two hydroxyl groups on a benzene ring) and an amine (NH_2). Both of these catecholamine messengers play important roles in the regulation of diverse physiological systems by acting through adrenergic receptors. Stimulation of adrenergic receptors by catecholamines, released in response to activation of the sympathetic autonomic nervous system, results in a variety of effects such as increased heart rate, regulation of vascular tone, and bronchodilatation. In the central nervous system, adrenergic receptors are involved in many functions, including memory, learning, alertness, and the response to stress.

Norepinephrine is synthesized starting with the amino acid tyrosine, which is obtained from the diet and can also be synthesized from phenylalanine. Tyrosine is converted to dihydroxyphenylalanine (DOPA) by the enzyme tyrosine hydroxylase, and DOPA in turn is converted to dopamine. Dopamine is then converted to norepinephrine by the enzyme dopamine beta-hydroxylase. In the adrenal medulla and in a few brain

regions, norepinephrine is converted to epinephrine by the enzyme phenylethanolamine N-methyltransferase. The major mechanism by which the effects of norepinephrine are terminated is reuptake back into the nerve terminal by a high-affinity norepinephrine transporter. Epinephrine, as well as norepinephrine, are metabolized to inactive products. Norepinephrine is metabolized by the enzymes monoamine oxidase (MAO) and catechol-O-methyltransferase (COMT) to 3-methoxy-4-hydroxyphenylglycol (MHPG) and 3-methoxy-4-hydroxymandelic acid (VMA). The major metabolite found in the blood and urine is MHPG. Epinephrine is similarly metabolized by MAO and COMT to VMA.

Classification and Mechanism of Action of Adrenergic Receptors

Adrenergic receptors were originally divided into two major types, alpha and beta, based on their pharmacological characteristics (i.e., rank order potency of agonists). Subsequently, the beta adrenergic receptors were subdivided into beta-1 and beta-2 subtypes; more recently, a beta-3 subtype has been defined. The alpha adrenergic receptors were first subdivided into postsynaptic (alpha-1) and presynaptic (alpha-2) subtypes. After it was realized that not all alpha receptors with alpha-2 pharmacological characteristics were presynaptic, the pharmacological definition was used. The current classification scheme is based on three major types: alpha-1, alpha-2, and beta. Each of these three receptor types is further divided into three subtypes as shown in [Figure 1](#): alpha-1A, alpha-1B, alpha-1D; alpha-2A, alpha-2B, alpha-2C; and beta-1, beta-2, beta-3.

The binding of an agonist to an adrenergic receptor induces (or stabilizes) a conformational change that allows the receptor to interact with and activate a G protein. The activated receptor facilitates the exchange of guanidine diphosphate for guanidine triphosphate, leading to the dissociation of the α and $\beta\gamma$ subunits of the G protein, which in turn stimulate or inhibit the activity of various effectors. It is important to note

Figure 1 The classification scheme for adrenergic receptors.

that each of the three types of adrenergic receptors couples to a distinct class of G proteins: alpha-1 to G_q ; alpha-2 to $G_{i/o}$; and beta to G_s . In addition to G proteins, adrenergic receptors interact with other signaling proteins and pathways such as those involving tyrosine kinases.

Alpha-1 Adrenergic Receptors

Three genetic and four pharmacological alpha-1 adrenergic receptor subtypes have been defined. The alpha-1A and alpha-1B subtypes were initially defined based on their differential affinity for adrenergic agents, such as WB4101 and phentolamine, and on their differential sensitivities to the site-directed alkylating agent chloroethylclonidine. The alpha-1B subtype was subsequently cloned from the hamster and the alpha-1A was cloned from bovine brain, although it was originally called the alpha-1c adrenergic receptor. A third subtype, the alpha-1D adrenergic receptor, was subsequently cloned from the rat cerebral cortex, although this clone was originally called the alpha-1a subtype by some investigators. A fourth pharmacological subtype, the alpha-1L, has been identified in vascular tissues from several species, but it may represent a conformational state of the alpha-1A receptor. The current classification scheme includes the alpha-1A, the alpha-1B, and the alpha-1D, but there is no alpha-1 C (Figure 1).

Pharmacological and Molecular Characteristics of Alpha-1 Adrenergic Receptors

In addition to norepinephrine and epinephrine, alpha-1 receptors are activated by various agonists such as phenylephrine (neosynephrine) and methoxamine (Vasoxyl). These agonists are relatively selective for alpha-1 receptors and have low affinity for alpha-2 and beta receptors. By contrast, they have similar affinities for the three alpha-1 subtypes and are thus nonsubtype selectively agonists. Similarly, antagonists including prazosin (Minipress) and tamsulosin (Flomax) are relatively selective for alpha-1 receptors and block alpha-2 and beta receptors only at high concentrations. Several other antagonists such as phentolamine (Regitine) and phenoxybenzamine (Dibenzylamine) block both alpha-1 and alpha-2 adrenergic receptors with similar affinities. Alpha-1A selective

antagonists include 5-methylurapidil and niguldipine, whereas cirazoline appears to be a selective alpha-1A agonist.

The alpha-1 adrenergic receptors are single polypeptide chains of 446–572 amino acid residues that span the membrane 7 times, with the amino terminal being extracellular and the carboxy terminal intracellular. Thus, there are three intracellular loops and three extracellular loops. In contrast to the alpha-2 receptors, but similar to the beta receptors, the alpha-1 receptors have a long carboxy terminal tail (137–179 amino acid residues) and a short third intracellular loop (68–73 amino acid residues). The amino terminal of the alpha-1A and alpha-1B subtypes have three (alpha-1A) or four (alpha-1B) consensus sites for N-linked glycosylation. The carboxy terminal tails of all three subtypes are potentially palmitoylated, thus anchoring the tail to the membrane and forming a small fourth intracellular loop. The carboxy terminal tails also have multiple sites of phosphorylation that are thought to be important in the desensitization, recycling, and downregulation of the receptor.

The human alpha-1 adrenergic receptor genes consist of two exons and a single large intron of at least 20 kb in the region corresponding to the sixth transmembrane domain. No splice variants are known for the alpha-1B and alpha-1D subtypes. By contrast, at least 10 splice variants of human alpha-1A subtype have been reported, but only four produce full-length receptors.

Alpha-2 Adrenergic Receptors

Three genetic and four pharmacological alpha-2 adrenergic receptor subtypes have also been defined (Figure 1). The alpha-2A and alpha-2B subtypes were initially defined based on their differential affinity for adrenergic agents such as prazosin and oxymetazoline. These subtypes were subsequently cloned from human, rat, and mouse. A third subtype, alpha-2 C, was originally identified in an opossum kidney cell line and has also been cloned from several species. A fourth pharmacological subtype, the alpha-2D, has been identified in the rat, mouse, and cow. This pharmacological subtype is a species ortholog of the human alpha-2A subtype, and thus it is not a separate genetic subtype.

Pharmacological and Molecular Characteristics of Alpha-2 Adrenergic Receptors

In addition to norepinephrine and epinephrine, alpha-2 receptors are activated by clonidine (Catapres) and brimonidine (Alphagan). These agonists are relatively selective for alpha-2 receptors and have lower affinity at alpha-1 and beta receptors. Similarly, the antagonist yohimbine is relatively selective for alpha-2 receptors and blocks alpha-1 and beta receptors only at higher concentrations. Antagonists that are at least somewhat selective for one of the alpha-2 subtypes include BRL44408 for the alpha-2A, prazosin and ARC-239 for the alpha-2B (note, however, that these two agents have much higher affinities for alpha-1 receptors), and rauwolscine for the alpha-2 C subtype. Oxymetazoline is a partial agonist that has a higher affinity for the alpha-2A subtype when compared to the alpha-2B and alpha-2 C subtypes.

The alpha-2 adrenergic receptors are single polypeptide chains of 450–462 amino acid residues. In contrast to the alpha-1 and beta receptors, the alpha-2 receptors tend to have long third intracellular loops (148–179 amino acid residues) and a short carboxy terminal tail (20–21 amino acid residues). The amino terminal of the alpha-2A and alpha-2C subtypes has two consensus sites for N-linked glycosylation, and the carboxy terminal tails of all three subtypes are potentially palmitoylated. The third intracellular loops have multiple sites of phosphorylation, which are thought to be important in the desensitization, recycling, and downregulation of the receptor. The alpha-2 adrenergic receptor genes do not contain introns, and thus there are no splice variants.

Beta Adrenergic Receptors

Three beta adrenergic receptor subtypes have been identified. The beta-1 adrenergic receptor, the dominant receptor in heart and adipose tissue, is equally sensitive to epinephrine and norepinephrine, whereas the beta-2 adrenergic receptor, responsible for relaxation of vascular, uterine, and airway smooth muscle, is less sensitive to norepinephrine as compared to epinephrine. The beta-3 receptor is insensitive to the commonly used beta-adrenergic receptor antagonists and was previously referred to as the 'atypical' beta adrenergic receptor. A beta-4 receptor has been postulated; however, definitive evidence of its existence is lacking, and it is now thought to be a 'state' of the beta-1 adrenergic receptor.

Pharmacological and Molecular Characteristics of Beta Adrenergic Receptors

Isoproterenol (Isuprel) is the prototypic nonsubtype selective beta agonist that has no activity at alpha-1 and alpha-2 receptors except at high concentrations. Epinephrine is 10–100-fold more potent at the beta-2 receptor as compared to the beta-1 subtype, whereas norepinephrine is more potent than epinephrine at the beta-3 subtype. Many beta-2 selective agonists, such as terbutaline (Brethine) and salmeterol (Serevent), have been developed for the treatment of asthma. Due to their subtype selectivity, they have a lower incidence of side effects mediated by the beta-1 receptor. Propranolol (Inderal) is the prototypic nonsubtype selective beta antagonist that has equal affinities at the beta-1 and beta-2 subtypes. Other nonselective beta adrenergic antagonists include timolol (Blocadren), pindolol (Visken, which is actually a weak partial agonist), and carvedilol (Coreg), which is also an alpha-1 antagonist. Several beta-1 selective antagonists have been developed, such as metoprolol (Lopressor) and esmolol (Brevibloc).

The beta adrenergic receptors are single polypeptide chains of 408–477. In contrast to the alpha-2 receptors, but similar to the alpha-1 receptors, the beta receptors tend to have longer carboxy terminal tails (61–97 amino acid residues) and shorter third intracellular loops (54–80 amino acids). The amino terminal of the beta receptors have one or two consensus sites for N-linked glycosylation, and the carboxy terminal tails are potentially palmitoylated. The carboxy terminal tails also have multiple sites of phosphorylation, which are thought to

be important in the desensitization, recycling, and downregulation of the receptor. The crystal structure of modified beta-2 adrenergic receptors has been determined.

The beta-1 and beta-2 adrenergic receptor genes do not contain introns; thus, they have no splice variants. By contrast, the beta-3 receptor has one intron, resulting in two splice variants. However, no functional differences have been found between the two splice variants.

Regulation of Adrenergic Receptors

The processes involved in homologous desensitization and downregulation have been extensively investigated for the beta-2 adrenergic receptor. The other adrenergic receptors, as well as many other G-protein-coupled receptors, appear to behave in a similar manner. Initial uncoupling of the beta-2 receptor from the G protein after agonist binding is mediated by phosphorylation of specific residues in the carboxyl tail of the receptor. The phosphorylated beta-2 receptor serves as a substrate for the binding of β -arrestin, which not only uncouples the receptor from the signal transduction process but also serves as an adapter protein that mediates the binding of additional signaling proteins and entry into the internalization pathway. The mechanisms of beta-2 adrenergic receptor downregulation appear to involve both an increase in the rate of degradation of the receptor as well as a decrease in the levels of beta receptor messenger RNA (mRNA).

Adrenergic Receptor Signal Transduction Pathways

The alpha-1 adrenergic receptors activate the $G_{q/11}$ family of G proteins leading to the dissociation of the α and $\beta\gamma$ subunits and the subsequent stimulation of the enzyme phospholipase C. This enzyme hydrolyzes phosphatidylinositol 1,2-bisphosphate in the membrane producing inositol trisphosphate (IP_3) and diacylglycerol. These molecules act as second messengers mediating intracellular Ca^{2+} release via the IP_3 receptor and activating protein kinase C. Other signaling pathways that have also been shown to be activated by alpha-1 receptors include Ca^{2+} influx via voltage-dependent and -independent calcium channels, arachidonic acid release, and activation of phospholipase A_2 , phospholipase D, and mitogen-activated protein kinase.

The alpha-2 adrenergic receptors activate the $G_{i/o}$ family of G proteins and alter (classically inhibit) the activity of the enzyme adenylyl cyclase, which, in turn, decreases the concentration of the second messenger cyclic adenosine monophosphate (AMP). In addition, the stimulation of alpha-2 receptors can regulate several other effector systems including the activation of K^+ channels, inhibition or activation of Ca^{2+} channels, and activation of phospholipase A_2 , phospholipase C, and Na^+/H^+ exchange.

The beta adrenergic receptors activate the G_s family of G proteins and activate adenylyl cyclase, thus increasing cyclic AMP concentrations. Beta adrenergic receptors interact with many other signaling proteins, including the phosphoprotein EBP50 (ezrin-radixin-moesin-binding phosphoprotein-50), the Na^+/H^+ exchanger regulatory factor, and with CNrasGEF.

Adrenergic Receptor Polymorphisms

Polymorphisms have been identified in some of the alpha-2 and beta adrenergic receptor subtypes, which may have important clinical implications. A common polymorphism has been identified in the third intracellular loop of the alpha-2B receptor, which consists of a deletion of three glutamate residues (301–303) that results in a loss of short-term agonist-induced desensitization. This deletion is a risk factor for acute coronary events, but not hypertension. A common polymorphism has been identified in the third intracellular loop of alpha-2 C subtype, which consists of a deletion of four amino acid residues (322–325).

The gene encoding the human beta-1 adrenergic receptor is quite polymorphic with 18 single-nucleotide polymorphisms, 7 of which cause amino acid substitutions. A total of 13 polymorphisms in the beta-2 adrenergic receptor gene and its transcriptional regulator upstream peptide has been identified. Three closely linked polymorphisms, two coding regions at amino acid positions 16 and 27 and one in the upstream peptide, are common in the general Caucasian population. The glycine-16 receptor exhibits enhanced downregulation *in vitro* after agonist exposure. By contrast, arginine-16 receptors are more resistant to downregulation. Some studies have suggested a relationship among these polymorphisms, airway responsiveness (e.g., asthma), and the responsiveness to beta adrenergic agonists.

A tryptophan-64 to arginine polymorphism has been identified in the beta-3 adrenergic receptor. The allele frequency is approximately 30% in the Japanese population, higher in Pima Indians, and lower in Caucasians. Type 2 diabetic patients with this mutation showed a significantly younger onset age of diabetes and an increased tendency to obesity, hyperinsulinemia, and hypertension.

Glossary

Epitope tag A short polypeptide fused to a protein of interest so that it will be recognized as a high-affinity binding target by a specific, well-characterized antibody.

Fusion protein A polypeptide made from a recombinant gene consisting of two or more gene fragments fused together.

Immobilized metal-affinity chromatography

(IMAC) A type of affinity chromatography based on the specific interaction between a metal chelate stationary phase and a metal-binding peptide fused to a protein of interest.

Applications of Affinity Tags

Affinity tags have proved to be tremendously effective tools for a wide variety of applications, and they are now incorporated as a standard feature to reduce the number of steps in purification protocols developed for recombinant proteins. In addition, affinity tags have become indispensable in the immobilization of proteins for display on a surface, where the tag ensures that the fusion protein of interest is oriented with its functional regions exposed to docking with other macromolecules. Affinity tags are also used to detect and quantitate target proteins and to analyze protein–protein or protein–ligand interactions. Related technologies are developing rapidly, including bioreactors for multistep enzymatic reactions and bioadsorbents for extraction or degradation of toxic contaminants.

Construction of a Fusion Protein

An affinity-tagged fusion protein typically consists of a single polypeptide chain with one or more affinity tags coupled to the C- or N-terminus of the target protein or inserted into a loop region. The coupling is via a peptide linker, usually up to 15 amino acids in length. If desired, the linker can contain a specific protease site for affinity tag removal. The use of multiple tags is increasingly common and endows the target protein with two or more unique molecular handles.

Selection Criteria for an Affinity Tag

Construction of a fusion protein begins with the selection of an affinity tag that is appropriate for the protein of interest (see below). The selection criteria include the size of the affinity tag, the organism that will be used to express the fusion protein, conditions for the immobilization or purification of the fusion protein, and the influence of the affinity tag on the structural and functional characterization of the target protein.

Affinity-Fusion Gene Constructs

To incorporate the selected affinity tag, a suitable expression plasmid vector is chosen and recombinant DNA techniques are

used to insert the target gene next to the affinity tag gene. Numerous vectors are commercially available that code for a selected affinity tag and a linker peptide, the latter often containing an imbedded protease recognition sequence. In addition, an inducible promoter is present to enhance and regulate fusion protein expression, and a multiple cloning site region is included to facilitate insertion of the target gene with the fusion site at the C- or N-terminus as desired. In some cases, the coding region for a signal peptide is included to promote the secretion of the fusion protein into a specific cellular compartment or into the extracellular medium. Newly developed vectors fuse two different tags to each terminus of a target protein, thereby allowing two-step isolation schemes with enhanced purity and ensuring that only fully intact forms of the fusion protein are isolated.

Linker Peptide Composition

The composition of the linker peptide can have a substantial impact on the function and utility of the fusion protein; therefore, a number of factors are considered during linker design. Typically, the linker is at least 5–10 residues long to allow free tumbling of the fusion and target proteins relative to one another, thereby preventing unwanted steric hindrance to binding events. For linkers containing a proteolytic cleavage site (typically for enterokinase, factor Xa, thrombin, or tobacco etch virus (TEV)), inclusion of 5–10 flanking amino acids at both ends of the site ensures adequate accessibility to protease. Finally, the linker amino acid composition must be selected to minimize susceptibility to host organism proteases.

Overview of Fusion Protein Production and Immobilization

Purification of a recombinant fusion protein begins with the introduction of the expression plasmid into the host cell, followed by cell growth and induction of the fusion promoter. The host cells are lysed and the resulting lysate, containing the affinity-tagged protein, is incubated with a solid-phase support to which the binding partner is coupled. Following binding of the tag to its immobilized partner, the support is washed

to remove unbound components, yielding specific isolation of the tagged protein. If desired, the tagged protein can be released by either disrupting its interaction with the binding partner or by proteolysis of the linker region. Isolation and immobilization procedures often need to be optimized for each new affinity-tagged protein and expression host.

Features and Types of Affinity Tag Systems

The large number of affinity tags currently available offers a diverse spectrum of biochemical properties that can be exploited for protein immobilization in a variety of contexts. Affinity tags range in size from short peptides less than 1 kDa to proteins as large as 120 kDa, and they can be classified into general categories based on their binding partner interaction such as protein–ligand, polyamino acid–matrix, antigen–antibody, and protein–protein. New types of tags based on novel binding partner interactions continue to emerge at a rapid pace.

When choosing an affinity tag for a specific application, several features are considered. A subset of affinity tags possesses the useful property of binding to their partner even under denaturing conditions. The ability to immobilize a tagged protein under denaturing conditions is a great advantage when the fusion protein is expressed in an insoluble or non-native form. Other tags utilize a binding partner interaction that is easily disrupted under mild conditions, thereby facilitating the recovery of target protein with full biological activity. Affinity tag size can also impact target protein function and structural integrity. Small tags generally have less impact on protein structure and function and often need not be removed, while large tags can be perturbing and thus are typically removed prior to structural and functional studies. On the other hand, certain large tags can significantly enhance the solubility of a fusion protein expressed at high levels; therefore, they are appropriate choices for the isolation of poorly soluble target proteins. Finally, when a target protein is toxic to the expression host, affinity tags that promote the aggregation of fusion protein into insoluble aggregates known as inclusion bodies are used. Key features of representative affinity tags are discussed below, and [Table 1](#) presents a more comprehensive list.

Protein–Ligand Interaction Affinity Tags

Enzymes and small-molecule-binding proteins are designed to bind their ligands with high specificity; thus, many highly effective affinity tag systems are based on ligand-binding interactions. One of these is the widely utilized glutathione S-transferase (GST) tag (26 kDa) that binds with high specificity and low affinity ($K_D \sim 180 \mu\text{M}$) to its substrate glutathione. Although the affinity of the GST tag for its ligand is low, commercially available immobilized glutathione matrices provide high local ligand concentrations that ensure adequate retention of the fusion protein. GST-tagged proteins are typically isolated from crude cell lysates by their interaction with immobilized glutathione on beads and then eluted by competitive displacement with free, reduced glutathione. The low ligand affinity enables elution under mild, nondenaturing conditions.

The GST tag often increases fusion protein solubility and stability, and it is ideally suited for overexpression of recombinant proteins in their native state. Often, the GST tag is proteolytically removed at the end of the purification due to its large size and tendency to form dimers. In other applications, the GST tag is retained and used to couple the target protein to a bead or surface for biochemical or biophysical studies.

Another family of affinity tags that relies on protein–ligand interactions are the cellulose-binding domains (CelBDs). CelBDs are small, highly stable protein modules consisting of between 33 and 180 amino acids (3–20 kDa) that bind to different forms of cellulose or chitin with a broad range of affinities ($K_D \sim 0.01\text{--}400 \mu\text{M}$). CelBD fusions can be constructed with affinity tags inserted internally or linked to either the C- or N-terminus of the protein of interest. Over 180 different CelBDs have been identified, providing a spectrum of polysaccharide specificities, binding affinities, and targeting properties. Certain CelBDs bind cellulose essentially irreversibly, making them ideal for protein immobilization, while other CelBDs exhibit easily reversible binding. Denaturing conditions or proteolysis are often needed to elute irreversible CelBDs, while reversible CelBDs can be eluted under mild conditions such as the use of a competitive ligand (cellulose or ethylene glycol) or desorption with water. Finally, CelBDs can be selected that target the fusion protein for secretion or inclusion body formation.

The 51-amino-acid chitin-binding domain (ChiBD) is derived from *Bacillus circulans* chitinase and exhibits high-affinity, essentially irreversible binding to its ligand chitin, a natural carbohydrate polymer. ChiBD fusion proteins are immobilized under physiological conditions by adsorption to chitin coupled to a solid-phase material. ChiBD fusion proteins often have an intein element incorporated into the linker region in place of a proteolytic recognition sequence. When remobilization of the fusion protein is desired, the intein element is activated and undergoes self-cleavage, resulting in the release of the target protein, while the intein–ChiBD region is retained on the solid phase. Similar inteins will probably soon be incorporated into the linkers of other affinity tags. Several other protein–ligand affinity tag systems are currently in use, each having unique advantages. For example, the 40-kDa maltose-binding protein (MalBP) is a large tag that often increases fusion protein solubility. MalBP binds to cross-linked amylose with moderate affinity (K_D in micromolar range), permitting MalBP-tagged fusion proteins to be immobilized in a reversible fashion. The full-length MalBP tag directs a fusion protein to the oxidizing *Escherichia coli* periplasm, where MalBP is a native protein and where the fusion protein may benefit from disulfide bond formation. Alternatively, removal of the MalBP leader peptide yields retention of the fusion protein in the cytosol, where the greater volume can allow higher expression levels.

Polyamino Acid–Matrix Interaction Affinity Tags

Immobilized-metal affinity chromatography (IMAC) is a common technique used to purify recombinant proteins fused to a short peptide affinity tag. IMAC, which can be carried out under denaturing or nondenaturing conditions, relies on the interaction between multiple electron donors on the affinity

Table 1 Commonly used affinity tags and their features

Category of tag	Name of tag	Number of residues in tag	Size of tag (kDa)	Location of tag	Immobile phase-binding partner	Nondenaturing		Expression host ^a
						Immobilization conditions	Affinity tag elution conditions (eluent)	
Protein–ligand interactions	Glutathione S-transferase	211	26	N-term, C-term	Glutathione	Yes	Yes (10 mM Reduced glutathione)	B, Y, I, M
	Cellulose-binding domains	27–189	3–20	N-term, C-term, Internal	Cellulose and other cellulotics	Yes	Yes (water) or no (guanidinium HCL)	B, Y, I, M
	Maltose-binding protein	396	40	N-term, C-term	Cross-linked amylose	Yes	Yes (10 mM maltose)	B
	Chitin-binding domain	51	5.6	N-term, C-term	Chitin	Yes	No	B
Polyamino acid–matrix interactions	Polyhistidine	6–12	0.8–1.7	N-term, C-term, Internal	Metal chelate	Yes or no (denaturants)	Yes (imidazole) or No (low pH)	B, Y, I, M, P
	Polyarginine	5–15	0.8–2.4	C-term	Cation-exchange resin	Yes	Yes (NaCl gradient at alkaline pH)	B, P
Antibody–epitope interactions	Hemagglutinin (HA)	9	1.1	N-term, C-term	IgG	Yes	No (low pH)	Y, M
	T7	11	1.1	N-term	IgG	Yes	No (low pH)	B, Y, M, P, I
	Synthetic protein A (Z domain)	58	7	N-term	IgG	Yes	No (low pH)	B, Y, I, M, P
Protein–protein interactions	FLAG	8	1.0	N-term, C-term	mAb M1 and mAb M2	Yes	Yes (EDTA)	B, Y, I, M, P
	c-myc	11	1.2	N-term, C-term	IgG	Yes	Yes (free c-myc epitope)	B, Y, I, M, P
	Biotin	~20–100	~2–11	N-term, C-term	Modified avidin or streptavidin	Yes	Yes (20 mM biotin)	B, I, M
	Calmodulin-binding peptide	26	3	N-term, C-term	Calmodulin	Yes (+Ca ²⁺)	Yes (+EGTA)	B
	Strep-tag II	8	1.1	N-term, C-term, internal	Strep-tactin	Yes	Yes (desthiobiotin)	B, Y, I, M, P
	Streptavidin-binding peptide	38	4	C-term	Streptavidin	Yes	Yes (biotin)	B
	Thioredoxin	109	11.7	N-term, C-term	Phenylarsine oxide-agarose	Yes	Yes (β -mercaptoethanol)	B
	His-patch thioredoxin	109	11.7	N-term, C-term	Metal chelate	Yes or no	Yes (imidazole) or no (low pH)	B
	S-tag	15	1.8	N-term, C-term	S-protein	Yes	Yes (2 M sodium thiocyanate)	B, I, M

^aB, bacteria; Y, yeast; I, insect; M, mammalian; P, plant.

tag with a transition metal ion (Co^{2+} , Ni^{2+} , Cu^{2+} , Zn^{2+}) chelated to a solid-phase support. The affinity tag is typically polyhistidine, ranging 6–12 residues in length fused to the N- or C-terminus of the target, where 6-His is most common and the electron donor is the histidine imidazole ring. Recently, an affinity tag based on a natural peptide derived from the N-terminus of chicken lactate dehydrogenase has also been utilized. This HAT-tag contains six histidine residues interspersed within a 19-residue polypeptide (KDHLI HNVHK EEHAH AHNK) that binds to specifically Co^{2+} -carboxymethyl-aspartate and has a lower net charge than polyhistidine tags. The most widely employed metal chelator is iminodiacetic acid (IDA), while nitrilotriacetic acid (NTA) and carboxymethylated aspartic acid (trade name TALON) are also popular. The chelator is generally covalently coupled to polymer beads, or ferromagnetic beads for magnetic isolation. Adsorption of IMAC-tagged proteins is normally performed at neutral to slightly basic pH to ensure that the histidine imidazole groups are not protonated. Mild elution conditions include ligand exchange with imidazole, extraction of the metal ion by a strong chelator like ethylene diamine tetraacetic acid (EDTA), or proteolytic elution. Low pH will also elute, but it can sometimes denature the target protein. IMAC is not recommended for target proteins possessing a metal center, since the metal can be stripped by the binding partner chelators.

The Arg-tag is another example of a small polyamino acid affinity tag, in this case designed to raise the isoelectric point of the fusion protein to enhance its binding to a cation-exchange matrix. Mild elution conditions are generally a NaCl gradient at alkaline pH. This tag also binds to flat mica sheets, which may enable a variety of new applications.

Antibody–Epitope Interaction Affinity Tags

Recombinant DNA technology has been employed to create peptide epitopes that bind well-characterized antibodies. This process is known as epitope tagging and is complementary to a more traditional approach where a novel antibody is generated for an existing epitope. Both approaches have been exploited to develop affinity tag systems based on the binding interaction between a peptide epitope and its specific antibody partner. In some cases, several antibodies with different properties are available for a given epitope. Proteins fused to peptide epitope affinity tags can be captured by immunoaffinity interactions via immobilized monoclonal antibodies. Typical epitope tags range from 6 to 30 residues in length, are highly charged, and have little effect on protein structure–function. They can be fused at either the C- or N-terminus, or even inserted within the protein of interest. Epitope tag expression vectors are commercially available for mammalian, insect, yeast, and bacterial host cells and provide a variety of tags, including c-myc, FLAG, HA, T7, V5, vesicular stomatitis virus-G (VSV-G), recA, Protein C, Protein A, and Protein Z. Some of these are optimized for immobilization while others are primarily used for protein detection. The importance of epitope tags is illustrated by their many applications including analysis of *in vivo* protein expression, subcellular localization of gene products, determination of protein topology, cellular trafficking studies, and the investigation of protein–protein interactions. They are also important in protein purification and immobilization.

Antibody-binding partners are covalently coupled to agarose chromatography resins or magnetic glass beads. Immobilized antibodies tend to be less stable than many other affinity-binding partners due to their need for native structure. Elution under mild native conditions can be achieved by competitive displacement with free epitope, by proteolysis, or by exposure of the Ca^{2+} -dependent FLAG-tag to EDTA.

Protein–Protein Interaction Affinity Tags

Several high-affinity and high-specificity protein–protein interactions identified in biological systems have been adapted for use as affinity tags. *In vivo* biotinylation enzymatically couples biotin, a small-molecule vitamin, to a protein acceptor domain. The resulting modified protein provides an interesting example of a natural affinity tag. A number of well-characterized protein sequences are enzymatically biotinylated *in vivo*. These natural peptides of approximately 100 residues have been used as fusion tags that direct *in vivo* biotinylation of a fusion protein in a site-specific manner. In addition, shorter synthetic peptides (approximately 20 residues) known as biotin acceptor peptides (BAPs) have been developed for use as biotin affinity tags.

The high-affinity, specific interaction between biotin and either avidin or streptavidin ($K_D \sim 10^{-15}$ M) serves as the basis for immobilization. Biotin-tagged fusion proteins are typically captured by binding to monomeric avidin or streptavidin coupled to a chromatography matrix or other surface. Elution with free biotin requires harsh conditions that can be detrimental to the target protein, but proteolytic elution can be carried out under mild conditions. Alternatively, the biotin-tag fusion can be immobilized to modified forms of avidin or streptavidin that exhibit lower biotin affinity. Elution can then be conducted under nondenaturing conditions by competitive displacement with free biotin or alkaline pH.

Other examples of protein–protein affinity tags include the Strep-tag, the calmodulin-binding peptide (CalBP), and the S-tag. The Strep-tag is a nine-amino-acid peptide that was developed as an artificial ligand for streptavidin. Further refinements to these molecules yielded the eight-amino-acid peptide Strep-tag II and a mutant form of streptavidin called Strep-Tactin capable of moderate-affinity binding ($K_D \sim 1 \mu\text{M}$). Strep-tag fusion proteins are bound to streptavidin under physiological conditions and are efficiently displaced by free biotin or a biotin derivative. The mild conditions used for binding and elution enable Strep-fusions to be utilized in their native state. This small, stable, and nonperturbing tag is ideal for many applications in which a small tag is required, and for applications where detection of the fusion protein on a Western blot or by enzyme-linked immunosorbent assay (ELISA) is desired. Moreover, as the Strep-tag is not itself a metalloprotein and its elution does not require metal chelators, it is well suited for metalloprotein applications.

The 26-amino-acid CalBP was derived from the C-terminus of skeletal muscle light-chain kinase. The CalBP binds to calmodulin with high affinity ($K_D \sim 1 \text{ nM}$) in the presence of low CaCl_2 concentrations ($\geq 0.2 \text{ mM}$). The binding partner, calmodulin, is commercially available linked to chromatography resins that are used to immobilize CalBP fusions. CalBP fusion proteins are eluted under mild conditions by a Ca^{2+} chelating agent such as ethylene glycol tetraacetic acid (EGTA). CalBP

fusions are primarily expressed in *E. coli* that lacks calmodulin family members and thus possesses no sequences evolved to bind to calmodulin. Eukaryotic cells are not recommended for expression of CalBP-tagged proteins due to their large number of endogenous proteins (~30) that bind to calmodulin.

The S-tag protein fusion system consists of the S-peptide and its binding partner, the S-protein, both derived from RNAase A. The S-tag binds to the S-protein with moderate affinity ($K_D \sim 100$ nM), resulting in a strong interaction that is influenced by pH, temperature, and ionic strength. A unique feature of the S-tag system is that ribonucleolytic activity is restored when the S-peptide is bound to the 103-amino-acid S-protein. This enzymatic activity is exploited to measure the molar concentration of the S-tag fusion protein down to 20 fM in a highly sensitive and rapid assay. S-protein-based reagents have been developed to probe sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) blots for S-tag fusions employing colorimetric or chemiluminescent detection of the target protein down to nanogram quantities.

Glossary

Catalytic H-cluster The catalytic core of the [FeFe]-hydrogenase (HydA), termed the 'H-cluster', exists as a [4Fe-4S] subcluster linked by a cysteine thiolate to a modified 2Fe subcluster with unique nonprotein ligands.

Fuel cells An electrochemical cell that converts a source fuel into an electrical current. It generates electricity inside a cell through reactions between a fuel and an oxidant, triggered in the presence of an electrolyte.

Photobioreactor A transparent reactor that allows growth of cells under illumination; this term mostly refers to closed systems that have no direct exchange of gases and contaminants with the environment, as opposed to open ponds.

Radical SAM proteins A novel protein superfamily with over 600 members that catalyze diverse reactions, including unusual methylations, isomerization, sulfur insertion, ring formation, anaerobic oxidation, and protein radical formation.

Introduction

Fossil fuels have been utilized as a source of energy for many centuries, resulting in congestion, pollution, and growing environmental stress. Global oil supplies are rapidly being depleted and production levels are increasingly being reported to be close to their peak. More importantly, zero CO₂ emission fuels are becoming increasingly important due to the constraints of global climate change. Therefore, the development of new systems to produce these fuels is one of the greatest challenges facing our society. Solar energy is the most abundant and accessible renewable energy source available for future sustainable production of fuel and electricity. For effective use of solar energy, it is important to develop more cost-effective systems with the improved ability to convert solar energy into chemical energy. In this context, hydrogen (H₂) is considered to be a promising, clean energy carrier for future technologies. The fact that the burning of H₂ produces only H₂O increases its attractiveness, particularly in light of recent advances in hydrogen fuel cell technology. The direct photoproduction of H₂ by cyanobacteria and green algae is an alternative to utilizing the reductant generated from photosynthetic water reduction for the fixation of CO₂ into carbon-containing molecules.

Hydrogen metabolism is primarily the domain of bacteria and microalgae. Within these groups, it involves many taxonomically diverse species, a variety of enzymes, and several metabolic pathways and processes. Green algae and cyanobacteria are photoautotrophic organisms; they can grow under only sunlight and CO₂, without organic sources of carbon. It has been known for more than 60 years that, under anaerobic conditions, unicellular green algae can metabolize H₂, either by uptaking it and using it as an electron donor in CO₂-fixation, or by evolving H₂ in the light. Indeed, hydrogenase enzymes that either uptake or evolve H₂ have been found in many green algae. This article briefly examines green algal hydrogen metabolism and how it can be adapted for commercial H₂-production processes.

Green Algal Pathways for H₂ Production

The unicellular alga *Chlamydomonas reinhardtii* belongs to the group of eukaryotic green algae and lives in freshwater or in moist places. In addition to photosynthesis, unicellular green algae are able to perform many biotechnologically interesting metabolic reactions, such as fermentation and hydrogen photoproduction. The starting point for all biological solar-driven H₂-production methods is the process of photosynthesis (see [Figure 1](#)). Oxygenic photosynthesis involves a sequential chain of reactions that include light absorption, charge separation, electron transport, and dark CO₂ fixation. Oxygenic organisms harness solar energy to extract electrons from H₂O, which are required for CO₂ fixation. Electrons generated from H₂O molecules at photosystem II (PSII) are transferred to the cytochrome *b6/f* complex (*b6f*) and subsequently delivered to photosystem I (PSI). Through PSI, the electrons are transferred to ferredoxin (Fd) (a 2Fe-2S protein). Normally, Fd shuttles electrons to the enzyme ferredoxin-nicotinamide adenine dinucleotide phosphate (NADP)-oxidoreductase (FNR) that reduces NADP⁺ to NADPH, the direct source of reductant to convert CO₂ into carbohydrates in the Calvin-Benson cycle. Concomitantly, protons (H⁺) are carried from the stromal to the lumenal side of the thylakoids, creating a proton gradient across the thylakoid membrane, which is utilized by the enzyme adenosine triphosphate (ATP) synthase to generate the ATP that is also required for CO₂ fixation. Under anaerobic conditions, reduced Fd efficiently binds to an [FeFe]-hydrogenase and donates electrons to its catalytic site, known as the 'H-cluster' (HC). The function of the hydrogenase is to combine protons (H⁺) and electrons (e⁻) to form and release molecular H₂. Photosynthetic reducing power can thus be partitioned between at least two pathways: CO₂ reduction (under aerobic conditions) and H₂ production (under anaerobiosis). It is important to point out that CO₂ reduction requires ATP, whereas H₂ photoproduction does not. Instead, the latter is downregulated in the absence of ATP production (see [section H₂ Production: Issues and Challenges](#)). As expected, removal

Figure 1 Photosynthetic electron transport pathways in the green alga, *Chlamydomonas reinhardtii*. Photosynthesis extracts electron from H₂O and via the electron transport chain delivers them to the [FeFe]-hydrogenase where H₂ is generated. The red circles denote the major barriers limiting technological use of algae for photobiological H₂ production. Adapted from Ghirardi ML and Mohanty P (2010) Oxygenic hydrogen photoproduction – current status of the technology. *Current Science* 98: 499–507, with permission from Current Science.

of CO₂ from the headspace enhances light-driven H₂-evolution, indicating competition for electrons between the CO₂-fixation and the H₂-evolution processes.

Oxygenic H₂ photoproduction results in the simultaneous generation of H₂ and O₂ in an ~2:1 ratio as long as O₂ is continuously removed from the headspace. In the absence of active removal of O₂, this mechanism can operate for only 30–90s since O₂ is a powerful inhibitor of the [FeFe]-hydrogenase reaction (and it is also a suppressor of [FeFe]-hydrogenase gene transcription, which is discussed in detail in later sections).

An alternate source of electrons for H₂ photoevolution is endogenous substrate degradation. This pathway is dependent on the reduction of the plastoquinone (PQ) pool by NADH (released from the initial step of glycolysis), in a reaction catalyzed by the PQ/NAD(P)H-oxidoreductase. Light absorption by PSI and ensuing electron transport elevates the redox potential of these electrons to the redox equivalent of ferredoxin, thus permitting the generation of molecular H₂.

Enzymes for Algal Photohydrogen Production

Hydrogenases are enzymes capable of producing or uptaking molecular hydrogen. Hydrogenases are classified into three main groups, according to the cofactor(s) they contain in their catalytic site, as iron–iron [FeFe], nickel–iron [NiFe], or Fe-only hydrogenase. Algal hydrogenases belong to the class of [FeFe]-hydrogenases, they contain only Fe and S in their catalytic site, and are typically involved in H₂ production rather than H₂ oxidation. They catalyze the reversible reduction of protons to H₂:

[FeFe]-hydrogenases are small, monomeric enzymes of 45–49-kDa size containing a novel type of [Fe–S] cluster commonly referred to as the ‘H-cluster’ at their catalytic center. The HC comprises a conventional [4Fe–S] complex bridged by

the sulfur atom from a cysteine residue to a unique binuclear iron–sulfur subcluster. Three other cysteines coordinate the [4Fe4S]-center to the protein in all known [FeFe]-hydrogenases. Except for the bridging cysteine, the iron atoms of the 2Fe2S center are coordinated to carbon monoxide (CO) and cyanide (CN[−]) ligands, which are responsible for stabilizing the reduced form of the enzyme, and by a dithiomethylamine group linking the two S atoms. One of the CO groups is found in a position bridging both iron atoms when the enzyme is in an oxidized state, but its orientation has been proposed to change toward the distal Fe when the enzyme is in the reduced state. Highly conserved residues comprising several hydrophobic amino acids are thought to be involved in the formation of H₂ channels, thus connecting the catalytic site to the protein surface.

In *C. reinhardtii*, a monomeric [FeFe]-hydrogenase of 48 kDa (named HYDA1) with high specific activity was first isolated and biochemically characterized. More recent research revealed the presence and expression of a second [FeFe]-hydrogenase (HYDA2) in *C. reinhardtii* that is 74% similar and 68% identical to HYDA1. The transcripts for both hydrogenases, HYDA1 and HYDA2, are selectively expressed upon dark anaerobic incubation, suggesting regulation of gene expression by O₂. HYDA1, and most probably HYDA2, directly interact with reduced ferredoxin. The nucleus-encoded algal hydrogenases are synthesized in the cytosol as precursor proteins but the mature proteins are localized in the chloroplast stroma. A transit peptide domain that routes the [FeFe]-hydrogenases from the cytoplasm across the chloroplast envelope and into the chloroplast stroma has been identified at the N-terminal region of the enzyme.

[FeFe]-Hydrogenases Are Sensitive to O₂

The metallo-cluster of the [FeFe]-hydrogenases is very sensitive to O₂. This observation, together with the fact that hydrogenases are located in the chloroplast, where PSII releases O₂, causes H₂

production rates to be usually low. In algal cells, O_2 can adversely affect enzymatic activity by deactivating previously assembled [FeFe]-hydrogenases, and the isolated enzyme competes with CO for the same binding site in the HC of [FeFe]-hydrogenases. Oxygen inactivation is thought to occur by the direct interaction of O_2 with the [2Fe-2S] center on catalytic HC. In contrast to O_2 inactivation, inhibition by CO is largely but not entirely reversible. The nature of the final oxygen species bound to the inactivated enzyme is not known. However, it is known that diffusion of O_2 gas is necessary for the inactivation of the enzyme, since the catalytic site of the enzyme is embedded in the protein structure.

Melis and his coworkers in 2000 demonstrated a novel strategy to sustain green algal H_2 production in the light. The O_2 sensitivity of H_2 metabolism was bypassed in a two-stage process, in which O_2 -evolution and H_2 -evolution reactions were temporarily separated. In the first stage, normal photosynthesis, CO_2 -fixation, and release of O_2 upon oxidation of H_2O enabled green algae to survive. In the second stage, the authors selectively and partially inactivated the O_2 -evolving activity of PSII by incubating algal cultures in a sulfur-depleted medium. Since respiratory O_2 consumption is not affected by sulfur deprivation, inactivation of O_2 evolution facilitated the transition from the aerobic to an anaerobic state in a sealed photobioreactor. The establishment of anaerobiosis in the photobioreactor induced the expression of the two [FeFe]-hydrogenases in algal cells and inhibited the expression of ribulose-1,5-bisphosphate carboxylase oxygenase (Rubisco). This resulted in redirection of the flow of electrons from the photosynthetic electron transport chain in the chloroplast away from carbon fixation and towards proton reduction. As a consequence, sulfur-deprived algae were able to produce H_2 for a total of 3–4 days.

[FeFe]-Hydrogenase Maturation

Biosynthesis of an active [FeFe]-hydrogenase is a complex process. [FeFe]-hydrogenase maturation proteins were initially discovered in the green alga *C. reinhardtii*. Posewitz et al. showed that two novel radical S-adenosyl-methionine (radical SAM) proteins, HYDEF and HYDG, are required for *C. reinhardtii* [FeFe]-hydrogenase activity. Using a chemochromic sensor, a *hydef* mutant that was unable to produce hydrogen was isolated from a *C. reinhardtii* mutagenesis library. Moreover, the *HYDEF* gene was found to be adjacent to the *HYDG* gene, and both were shown to be present in all other [FeFe]-hydrogenase-containing organisms, although their role was unknown at that time. In the absence of a functional *HYDEF*, both hydrogenase structural genes were induced but no hydrogenase activity was detected in the mutant. Complementation of the mutant with genomic DNA containing a functional copy of the *HYDEF* gene restored hydrogenase activity in the algae. Later on, King et al. showed that the heterologous expression of active algal [FeFe]-hydrogenase in the bacterium, *Escherichia coli*, could be accomplished by co-transforming the *HYDA1* structural gene along with both the *HYDEF* and *HYDG* genes, and that all these genes were required and sufficient for the expression of a functional [FeFe]-hydrogenase in this bacterium. The algal *HYDEF* gene encodes for two unique protein

segments, HYDE and HYDF, that are exclusively found in other organisms containing [FeFe]-hydrogenase but encoded as two separate genes, *HydE* and *HydF*. The HydE proteins are highly homologous to the biotin synthase radical SAM proteins, and HYDF shares homology with the large family of nucleoside triphosphate (NTP)-binding proteins.

The specific role of HydE, HydF, and HydG proteins in [FeFe]-hydrogenase maturation is not clearly understood yet. Peters et al. proposed that the maturation proteins use common amino acids or other metabolites to synthesize a precursor to the [FeFe]-hydrogenase active site, which is then transferred to the structural enzyme. HydE and HydG act on HydF to assemble an active-site precursor containing all the nonprotein ligands of the binuclear Fe subcluster, which is subsequently transferred to the hydrogenase. It seems that HydE is probably responsible for the synthesis of CO and CN^- ligands and HydG for the dithiomethylamine ligand. The dithiomethylamine-bridged cluster is then transferred as a whole to HydF to generate a complete, functional HC for insertion to the [FeFe]-hydrogenase apoprotein.

The Interaction of [FeFe]-Hydrogenases with Ferredoxin

In green algae, H_2 production couples to the photosynthetic electron transport chain via ferredoxin. Ferredoxins are small soluble [Fe-S] proteins which can be found in every phylogenetic group. They are mainly low-potential electron carriers involved in various metabolic pathways having diverse redox partners. Ferredoxin distributes photosynthetic electrons not only to hydrogenase but also to other electron-dependent enzymes, the most important of which is ferredoxin-NAD(P)-reductase (FNR) for CO_2 fixation.

There are six ferredoxin genes in *C. reinhardtii*. The physiological regulation and metabolic function of each of the six ferredoxins has not yet been established, although it is assumed that both hydrogenases may associate with the photosynthetic electron transfer ferredoxin (PetF, also called FDX1) which is involved in photosynthesis and it is a typical plant-type [2Fe-2S] ferredoxin. Recently, Winkler et al. characterized the kinetics of electron transfer processes between HydA1 and PetF. Using an *in vitro* system by reconstituting part of the photosynthetic electron transport chain consisting of plastocyanin, PSI, PetF, and [FeFe]-hydrogenase, they demonstrated that residue K396 of HydA1 is crucial for a successful binding and electron transfer between PetF and HydA1. However, other studies by Terauchi et al. found that each of the six *FDX* genes is differentially regulated in response to changes in nutrient supply and/or anoxia. In this regard, more detailed understanding of the hydrogenase-ferredoxin association mechanism and kinetics is necessary for engineering hydrogenase to divert a greater electron flux to the H_2 production pathway and thus to optimize photobiological H_2 production.

H_2 Production: Issues and Challenges

Photobiological H_2 production by *C. reinhardtii* has become an important research field because of its potential to be applied

in renewable energy production. To realize the economic potential of producing hydrogen photobiologically, several challenges must be overcome. Foremost, cellular metabolism and the basic biochemistry supporting this process must be understood. Following are the major issues and challenges that need to be addressed.

O₂ Sensitivity

The simultaneous photoproduction of H₂ and O₂ from H₂O in green algae depends on O₂ tolerance of the reversible hydrogenase enzyme. When oxygenic photosynthesis is active, and unless strict measures are taken to remove O₂, green algal H₂-production activity is transient owing to the rapid inactivation of the reversible hydrogenase by photosynthetic O₂. Sustained hydrogen production will only be possible when the hydrogenase enzyme remains active under O₂-evolving conditions. Different strategies for development of O₂ tolerant hydrogenases have included molecular engineering of the hydrogenases by either random or site-directed mutagenesis to remove O₂ sensitivity. The latter has mostly focused on physical restriction of O₂ access catalytic site by reducing the O₂ diffusion rate or shielding the active catalytic site. Although the results are encouraging from a scientific perspective in understanding enzyme structure and function, none of these approaches has yielded biotechnologically significant hydrogen-producing strains yet.

An alternative approach to sustain H₂ production in the light is to use sulfur deprivation to partially inactivate O₂ evolution, as discussed above. The novel application of this process has led to significant and sustainable light-dependent release of H₂ by algal cultures, although at low-conversion efficiencies due to limited PSII activity. Several approaches have been examined to increase the yield of hydrogen in *C. reinhardtii* under sulfur-deprived condition, including optimization of the light and pH conditions in the photobioreactors optimization of the medium composition and synchronization of cell division (see Figure 2). Kruse et al. reported a significant increase in the rate and duration of H₂ photoproduction in sulfur-deprived mutants that are starch over-accumulators and blocked in state transitions. Another advance related to the sulfur-deprived process came with the recent discovery of a mutant affected in sulfate permease activity, which is required for transport of sulfate into the chloroplast. This mutant is a potential candidate for H₂ photoproduction without the need to totally remove sulfate from the growth medium.

The reported rates of H₂ production by sulfur-deprived cultures is still far below the maximum potential rate of H₂ photoproduction for an algal system, mainly due to partial inactivation of PSII. Furthermore, the system is difficult to scale up and maintain. These challenges, which are related partly to the photobioreactor design, might be addressed by immobilizing the green algae. The immobilization technique effectively separates cells from the liquid phase, significantly increases the cell density and, as a consequence, allows for more efficient light utilization on a per area basis. Laurinavichene, et al. in 2006 demonstrated that sulfur-deprived, immobilized cells of a nonmotile mutant of *C. reinhardtii* on glass fibers significantly increase the duration of H₂ production. More recently, Kosourov and Seibert, demonstrated that

Figure 2 Photograph of the photobioreactor used for H₂ production from *Chlamydomonas reinhardtii* culture showing probes used for monitoring and the controlling the system. Hydrogen bubbles emanate toward the surface of the culture and are collected in a liquid-accumulating bottle (not shown).

immobilization of sulfur/phosphorous-deprived algae in thin Ca²⁺-alginate film matrices has extended H₂ photoproduction for more than 150 h and also increased the stability of H₂ photoproduction activity in the presence of atmospheric O₂. This work shows potential for further significant improvements in both the rate and efficiency of H₂ production under sulfur-deprived conditions.

Reduced Antenna Size

Photosynthesis and H₂ production in unicellular green algae can in principle operate with a nearly 100% photon utilization efficiency, making them potentially efficient biocatalysts for the generation of H₂ from sunlight and water. However, green algal cultures show poor light utilization efficiency under direct sun light and can waste up to 80% of the absorbed irradiance. The reason for this is that green algal photosynthesis normally saturates at about one-fifth of full sunlight intensity or less. This optical property of the cells would further lower the productivity of a commercial hydrogen production. Enhanced hydrogen production may be achieved by engineering the antenna size to suppress fluorescence and heat dissipation that causes a reduction on antenna efficiency.

Competition for Reductants

Competition from the CO₂-fixation pathway for electrons from H₂O is a major concern for sustained H₂ production, as discussed earlier in the article. This concern is based on the higher affinity of ferredoxin for FNR than hydrogenase, which could result in substantial drainage of electrons away from H₂ production. Therefore, improved H₂ production depends on interaction of [FeFe]-hydrogenases with the electron-carrying protein ferredoxin. Agapakis et al. fused the hydrogenase from *C. acetobutylicum* to ferredoxin from spinach or from

C. acetobutylicum using flexible protein linkers of various lengths and showed a threefold increase in H₂ production by a nonphotosynthetic, recombinant *E. coli* system. Moreover, chimeras between ferredoxin and various ferredoxin reductases have been shown to be functional *in vitro*, with improved electron transfer rates, presumably due to the increased local concentration of reduced ferredoxin. This approach may provide new targets for metabolic engineering of H₂ production in the future.

Downregulation of Electron Transport by the Proton Gradient

Under sulfur-deprived conditions, very little CO₂ is fixed into glucose, mainly because of the decrease in Rubisco levels. These sulfur-deprived, anaerobic cultures use very little ATP, as a consequence, the proton gradient generated by photosynthetic electron transport is not dissipated. This causes a decrease in the rate of electron transport as demonstrated by the acceleration in the rate of H₂ production observed upon addition of uncouplers. Although, mutants defective in one or other ATPase subunits have been generated, their uncoupling properties are yet to be studied. These mutants may be able to circumvent the cellular regulatory process that downregulate PSII activity at the level of the plastoquinone pool and limit H₂ production.

State Transition

Oxygenic photosynthetic organisms adapt to varying energetic requirements by transitioning between linear and cyclic electron transport, through the so-called state transitions. If the ATP requirement is higher than what is provided by linear electron transport alone, the cultures transition to state 2, where cyclic electron transport predominates. Anaerobiosis leads to the establishment of state 2 and, as a result, additional limitations are placed on the rates of H₂ photoproduction. The relevance of the state 2 limitation on H₂ photoproduction by sulfur-deprived culture was recently demonstrated by Kruse et al., who used a chlorophyll fluorescence video-imaging screening procedure to identify mutants of *C. reinhardtii* blocked in state 1. They isolated one mutant, *stm6*, with rates of H₂ photoproduction 13 times higher than its wild-type strain, and with extended H₂ photoproduction activity under sulfur deprivation. These results underscore the importance of molecular engineering to address this particular limitation to algal H₂ production technologies.

Conclusion

Biological hydrogen production is not only a challenging but also promising biotechnology area, with the potential to help solve environmental and energy-related problems. The application of biological H₂ production as a mature technology, however, depends on research advances to address improvements in H₂-production rates and efficiency through a combination of genetically engineering microorganisms and developing bioreactors. Significant progress is being made in understanding

the molecular regulation of the genes encoding hydrogenases and accessory proteins needed for assembly of hydrogenases, as well as in identifying and addressing the major barriers to a future commercial process. With increasing interest from the scientific community and the public in clean and renewable energy sources, rapid progress could bring this technology to fruition in the not-so-long future. Moreover, the possibilities and challenges within synthetic biology should be further explored for creating green algae with a high potential for H₂ production.

Allosteric Regulation

B S Cooperman, University of Pennsylvania, Philadelphia, PA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Allosteric effector A molecule binding to a protein site other than the active site, which can either increase or decrease the activity of the protein.

Heterotropic cooperativity The effect of an allosteric effector on protein activity toward a substrate.

Homotropic cooperativity The effect of initial substrate binding on subsequent substrate binding.

KNF and MWC models Thermodynamic models that account for the cooperativity displayed by allosteric enzymes.

Allosterism and Cooperativity

Allosteric regulation has been found to be extensive in proteins, particularly in enzymes at key branch points of metabolism and in receptors that must be sensitive to small variation in signals. Although a monomeric protein having one subunit can display allosteric regulation, the great majority of proteins regulated in this manner have multiple subunits, with changes in activity arising from changes in subunit-subunit contacts. A characteristic feature of these regulatory proteins is the occurrence of cooperative interactions for both the substrate and the regulatory ligand. This property renders their function dependent upon threshold concentrations of ligand.

Cooperative Binding of O₂ to Hemoglobin

Cooperativity may be defined as any process in which an initial event affects subsequent similar events. It was initially identified with the sigmoid plot for the binding of four molecules of O₂ to hemoglobin (Hb) (Figure 1), a pseudo-tetrameric protein that gives red blood cells their color. A similar cooperativity of substrate binding occurs in many allosteric enzymes, leading to sigmoid plots of enzyme activity versus substrate concentration. Hb has the subunit composition $\alpha_2\beta_2$, in which the α - and β -subunits are nearly identical to one another, with each containing a heme group to which O₂ binds. The sigmoid plot was explained by the concept that the first molecule of O₂ bound makes it easier for subsequent molecules to bind, and so is an example of positive cooperativity. In fact, if the Hb-binding curve is fitted to four successive binding constants, the affinity for the fourth O₂ bound is calculated to be 100–1000 times as high as the first O₂ bound. In contrast, O₂ binding to myoglobin (Mb), a monomeric protein found in vertebrate muscle with no possibility for site-site interaction, follows a rectangular hyperbola plot.

An essential feature of the positive cooperativity, shown in Figure 1 for Hb, is that it sharpens the responsiveness of a system to a change in substrate (or effector) concentration. Thus, to go from 10% to 90%, O₂ saturation of Mb requires an 81-fold change in O₂ concentration, whereas the corresponding change for O₂ saturation of Hb requires only a fourfold change. Such responsiveness is obviously desirable in a protein whose activity must be highly regulated.

The Hill n , a Measure of Cooperativity

The Hill plot linearizes saturation data over the major portion of the saturation curve (typically 10–90% saturation) yielding a slope, called the Hill n and denoted n_H , which provides a convenient empirical measure of cooperativity. If we define the saturation function Y_S as the fraction of all binding sites containing a bound ligand (i.e., $0 \leq Y_S \leq 1$), then the Hill plot is obtained by plotting $\log(Y_S/(1-Y_S))$ versus $\log[S]$ (when enzyme activity is measured, $\log(v/(V_{\max}-v))$ vs. $\log[S]$ is plotted instead). The value of n_H is 1 for a noncooperative saturation function (e.g., O₂ binding to Mb). Positive cooperativity is defined by an $n_H > 1$, with an upper limit of n , the number of identical subunits, for a cooperative saturation function. For a tetramer, an n_H equal to its upper limit of 4 would correspond to the situation where there were only two protein species in solution, one with no ligands bound and one with ligands bound to all four sites. For Hb, a strongly cooperative tetramer, the n_H value is near 3 under physiological conditions. Some allosteric proteins have $n_H < 1$, that is, have negative cooperativity. In contrast to positive cooperativity, negative cooperativity gives a less sensitive response over a broad range of stimulus and might be important, for example, in the response of growth or general metabolism to changes in hormone concentration.

One caveat to the use of n_H values evaluated from enzyme activity studies is that hysteresis or ligand-induced slow transitions that have the same timescale as the catalytic cycle can give rise to apparent cooperativity, even for monomeric enzymes. In addition, n_H values of <1 , whether determined by binding or enzyme activity studies, can arise from sample heterogeneity, rather than from true negative cooperativity.

Two-State Models to Explain Cooperativity in Allosteric Proteins

Two models were proposed in the 1960s to explain not only the cooperative binding of O₂ to Hb, and of substrate binding to allosteric proteins in general, but also the effects of allosteric effector molecules on substrate binding. Each of the models posits that the identical subunits within the protein can exist in two states, T and R , with the R state having higher activity for substrate. Here, some definitions are in order before proceeding further. O₂ binding to hemoglobin is an example of a

positive homotropic effect, since the initial binding of O_2 increases the affinity for subsequent O_2 molecules. On the other hand, addition of the allosteric inhibitor 2,3-diphosphoglycerate reduces O_2 affinity for Hb, providing an example of a negative heterotropic effect. In a similar fashion, an allosteric activator which increases substrate affinity gives rise to a positive heterotropic effect, whereas a negative homotropic effect is seen when initial binding of substrate decreases the affinity for subsequent substrate molecules.

The first model, proposed by Monod, Wyman, and Changeux in 1965, and known as the MWC (or symmetry) model hypothesizes that: (1) allosteric regulatory proteins, in general, are oligomers made up of a finite number of identical subunits that occupy equivalent positions and, as a consequence, possess at least one axis of rotational symmetry; (2) the allosteric oligomers can exist in two freely interconvertible and discrete conformational states (T or R) that differ in the energy of their intersubunit interactions, but in which molecular symmetry is conserved, so that all subunits are either in the T state or in the R state; (3) in the absence of ligand, the pre-existing conformational equilibrium is characterized by an allosteric constant $L = T_n/R_n$, where n is equal to the number of identical subunits; and (4) ligand affinities for the active and allosteric sites carried by the oligomers may differ between the two states, allowing ligand binding to preferentially stabilize the state for which it exhibits a higher affinity. Such modulation of the conformational equilibrium by ligand-binding suffices to generate positive homotropic effects and both positive and negative heterotropic effects.

The second model, proposed by Koshland, Nemethy, and Filmer in 1966, and known as the KNF (or sequential) model, hypothesizes that in the absence of ligand the protein exists in

a single state, that ligand-binding induces a conformational change only in the subunit to which it binds, and that cooperative interactions arise through the influence of such conformational changes on intersubunit interaction. The KNF model embodies the notion of induced fit, whereby the binding of substrate to an active site causes conformational changes of active site residues that are necessary for the protein's function. Since conformational change only occurs on ligand binding, partially saturated protein contains a mixture of R and T states, so that the symmetry of the oligomeric protein is not preserved during the binding process.

Both the MWC and KNF models are limiting cases of the more general scheme of a two-state model, as shown for the case of substrate binding to a tetrameric protein in Figure 2. In the MWC model, only species corresponding to the left-most (T_nS_i , $i = 0-n$) and right-most (R_nS_i , $i = 0-n$) columns are considered, because it is posited that hybrid states containing both R - and T -subunits are inherently unstable and do not accumulate. In contrast, in the KNF model, only species lying along the diagonal connecting T_n to R_nS_n (i.e., $T_{n-i}R_iS_i$, $i = 0-n$) are considered, because of the requirement that conformational change only results from substrate binding.

Either limiting model generates the sigmoidal saturation curve for substrate binding to an allosteric protein using just three parameters. For the MWC model these are L , the allosteric constant, and K_T and K_R , the dissociation constants for S binding to the T and R states, respectively. In the KNF model the three parameters are $K_S K_t$ (as a product), K_{RT} , and K_{RR} , where K_S is the binding constant for substrate to the R state, K_t is the equilibrium constant for changing a single, isolated, subunit from the T to the R conformation ($= [R]/[T]$), and K_{RT} and K_{RR} measure the relative strength of associations of R - T and R - R intersubunit contacts, respectively, versus the strength of association of T - T intersubunit contact. In the two models, allosteric effectors exert their heterotropic effects by altering the apparent

Figure 1 The O_2 -binding curves for Hb (cooperative) and Mb (noncooperative). The dashed line represents a noncooperative curve for O_2 binding having the same value as Hb for the O_2 pressure (pO_2) required for half-saturation ($YO_2 = 0.5$). Modified from Voet D, Voet JG, and Pratt CW (2002) *Fundamentals of Biochemistry*. New York, NY: Wiley.

Figure 2 The general two-state model for substrate binding to an allosteric tetrameric protein. The columns on the left and right show the species included in the MWC model. The diagonal from upper left to lower right shows the species included in the KNF model.

conformational equilibrium constant (L' or K'_l) in each model, with inhibitors, which bind T state preferentially, increasing L' or decreasing K'_l and activators, which bind R state preferentially, decreasing L' or increasing K'_l .

Because of their relative simplicities, both the MWC and KNF models provide useful frameworks for the analysis of allosteric proteins, although, in detail, each enzyme studied may show deviations. In some cases, one model may be preferred over the other. Thus, the MWC model does not account for negative homotropic effects ($n_H < 1$), whereas such effects can arise in the KNF model when K_{RT} is substantially greater than either K_{TT} or K_{RR} . On the other hand, the MWC predicts that the state function R , which measures the fraction of all subunits in the R state, will, in general, increase more rapidly as a function of substrate concentration than the saturation function Y_S , since the binding of one substrate molecule can shift all the subunits in T_n to the R_n conformation. In contrast, the KNF model demands that R is always equal to Y_S . Experimental examples have been found for both negative homotropic cooperativity and for $R \neq Y_S$. Detailed examination of structural or energetic changes on partial ligand binding has been used to differentiate between the two models.

Extensions and Modifications of Two-State Models

When ligand binding induces a change in the oligomeric state of the protein, cooperativity can result as a direct consequence of ligand binding preferentially to either the associated or dissociated form. If, for example, substrate binding favors a higher state of oligomerization, then higher enzyme concentrations will enhance activity but depress cooperativity, and, at constant enzyme concentration, allosteric ligands that favor association will be activators while those that favor dissociation will be inhibitors. The equations to account for this type of behavior are similar in form to those generated by either the MWC or KNF models, but with the addition of terms that are dependent on protein concentration.

Thus far, we have considered allosteric proteins in which the substrate and effector molecules have different affinities for the R and T states. These are the so-called K (binding constant) systems. In pure K allosteric enzymes, the T and R states have identical $V_{\max}$ values. However, allosteric enzymes can also be regulated by V (velocity) systems. In pure V allosteric enzymes, the R and T states have identical affinity for substrate but different $V_{\max}$ values. In both K and V enzymes, an effector functions by binding preferentially to the R or T state. For K systems, such binding results in altered affinity and cooperativity of substrate binding. In V systems, effector binding results in altered $V_{\max}$ values, and there is no cooperativity in substrate binding.

Structures of Allosteric Proteins

High-resolution structures have been determined for a number of allosteric enzymes in both the R and T states, permitting some generalizations to be made and allowing critical consideration of the MWC and KNF models. One common finding is that ligand-binding sites, both active site and regulatory, are located at subunit interfaces. Such placement provides an exquisite

means of communicating cooperative and/or allosteric effects between subunits in an oligomeric enzyme, since sites at the interface are likely to respond to the changes in subunit interactions that are critical for allosteric regulation. For similar reasons, a second common location for ligand binding is at the interface of two domains within the same subunit. Placement of the active site at either interface has as a consequence that even modest conformational changes can cause significant changes in the size and shape of the active site, thus altering the protein's activity. Allosteric binding sites also tend to be located in low-stability regions of the protein. The binding of an effector stabilizes both the region itself and specific contacts the region makes with adjacent regions, requiring the movements of polypeptide backbone and side chains, and, in particular, the alteration of salt bridges and hydrogen bonds at subunit interfaces. These movements provide a mechanism for transmission of signals to the active site and to other allosteric sites over distances of tens of angstroms. Other common features are: (1) small but critical movements at the active site; (2) the rotation of subunits with respect to one another around a cyclic axis; (3) only two modes of subunit:subunit docking, consistent with the MWC model of concerted transition; and (4) a more highly constrained and extensive subunit interface in the less active T -state than in the R -state.

Examples of Allosteric Proteins other than Hemoglobin

Aspartate Transcarbamoylase

Aspartate transcarbamoylase (ATCase) catalyzes a key step of pyrimidine biosynthesis, the condensation of carbamoyl phosphate with aspartate to form N -carbamoylaspartate. The *Escherichia coli* enzyme has been extensively studied. Cytidine triphosphate (CTP) is an allosteric inhibitor representing a classic case of feedback inhibition whereby the end product of a biosynthetic pathway inhibits an enzyme catalyzing a reaction at the beginning of the pathway. Adenosine triphosphate (ATP) is an allosteric activator, and together CTP and ATP act on ATCase to coordinate the rates of purine and pyrimidine nucleotide biosynthesis. The enzyme has the subunit composition c_6r_6 , where c and r are catalytic and regulatory subunits, respectively. The c subunits are arranged as two c_3 's, which are complexed with three r_2 's. In the absence of r subunits, the c subunits are catalytically active, and are unaffected by ATP or CTP, which bind only to the r subunit. Crystal structures have shown that the c_6r_6 holoenzyme exists in two conformations, with CTP preferentially binding to the inactive T state and ATP to the active R state. Interestingly, ATP and CTP bind competitively to the same allosteric site in the r subunit. CTP binding induces a contraction in r_2 , which in turn, via interactions at the r - c interface, results in the c_3 's moving together by 0.5 Å. This movement causes a perturbation of the active site and a loss in catalytic activity. In contrast, ATP binding results in the c_3 's moving apart by 0.4 Å.

Ribonucleotide Reductase

Ribonucleotide reductases (RRs) form a family of allosterically regulated enzymes that catalyze the conversion of ribonucleotides to deoxyribonucleotides and are essential for *de novo* DNA

biosynthesis. Their allosteric regulation is designed to match the flux of the four deoxynucleotides produced with the base composition of the organism's DNA. Class Ia RRs are the most widespread in nature. They accept the four common nucleoside diphosphates (NDPs) as substrates, with enzymatic activity dependent upon the formation of a heterocomplex between subunit R1, which contains the active site and three allosteric sites (the s-, a-, and h-sites), and subunit R2, which contains a stable tyrosyl-free radical that is necessary for NDP reduction at the active site. The substrate specificity of RR is determined by the allosteric ligand occupying the s-site. ATP and deoxy adenosine triphosphate (dATP) stimulate the reduction of CDP and uridine diphosphate (UDP), deoxythymidine triphosphate (dTTP) stimulates the reduction of guanosine diphosphate (GDP), and dGTP stimulates the reduction of adenosine diphosphate (ADP). The s-site is located at the interface between R1 monomers, such that effector binding drives formation of R1₂. The regulation of total enzyme activity is controlled by ATP and dATP, chiefly at the level of changes in oligomerization state. Both bind to the a-site, located at the interface between two R1₂'s, driving formation of R1₄, which exists in two conformations, R1_{4a} and R1_{4b}, with the latter predominating at equilibrium, while only ATP binds to the h-site, which drives formation of R1₆. Only the R2₂ complexes of R1₂, R1_{4a}, and R1₆ are enzymatically active. dATP is a universal inhibitor of RR activity due to its induction of R1_{4b} formation, whereas ATP is a universal activator because it induces R1₆ formation. Class II RRs, which are only found in bacteria, are considerably simpler, comprising only a monomeric protein containing an active site, an s-site, and a B₁₂ cofactor. Interestingly, the active site and s-site have the same relative orientations as in class Ia, with the s-site located at an interdomain interface.

GroEL

E. coli GroEL is an example of a chaperonin, which mediates protein folding in an MgATP-dependent manner. GroEL consists of 14 identical subunits that form two heptameric rings. Cooperativity in ATP binding and hydrolysis by chaperonins reflects the switching of rings between protein-binding and protein-release states and is important for regulation of their reaction cycle. GroEL displays two levels of allostery: one within each ring and the second between the two rings. In the first level of allostery, each heptameric ring is in equilibrium between *T* and *R* states that interconvert in a concerted manner, in accordance with the MWC model. In the absence of ligands, GroEL is predominantly in the *T*₇*T*₇ state. In the presence of low concentrations of ATP (<100 μM), the equilibrium is shifted toward the *T*₇*R*₇ state, displaying positive cooperativity in ATP binding and hydrolysis. A further shift in the equilibrium from the *T*₇*R*₇ state to the *R*₇*R*₇ state ($L2 = [RR]/[TR]$) takes place only at higher ATP concentrations because of inter-ring negative cooperativity. This second level of allostery is better described by the KNF model.

Cell-Surface Receptors Involved in Signal Transduction

Membrane receptors for transmitters, peptides, and pharmacological agents are central to signal transduction. They selectively recognize chemical effectors (neuronal or hormonal) and allosterically transduce binding recognition into biological action through the activation of ligand-gated ion channels (LGICs) and/or G-protein-coupled receptors (GPCRs). Various features of membrane receptors for neurotransmitters are well accommodated by the MWC model. These receptor proteins are typically heterooligomers and exhibit transmembrane polarity. In general, the regulatory site to which the neurotransmitter binds is exposed to the synaptic side of the membrane while the biologically active site is either a transmembrane ion channel, a G-protein-binding site, or a kinase-catalytic site facing the cytoplasm. Interactions between the two classes of sites are mediated by a transmembrane allosteric transition. Signal transduction or activation is mediated by a concerted cooperative transition between a silent resting state and an active state. Agonists stabilize the active state and competitive antagonists the silent state, and partial agonists may bind nonexclusively to both. These receptors can also undergo a cascade of slower, discrete allosteric transitions, which include refractory regulatory states that result in the desensitization or potentiation of the physiological response.

Glossary

Alternative exon A sequence of a gene that is included in some, but not all, mature mRNAs derived from that gene.

Alternative splicing Differential inclusion or exclusion of exons in a pre-mRNA substrate, which results in two or more mature transcripts being produced from a single pre-mRNA.

Constitutive exon A sequence of a gene that is included in all final mature mRNAs.

Pre-mRNA splicing The catalytic joining of exons and corresponding removal of intervening sequences (introns) from a pre-mRNA to produce a final mRNA.

Spliceosome A macromolecular ribonucleoprotein machine that catalyzes the removal of introns and ligation of exons in a pre-mRNA molecule.

Introduction

In higher eukaryotes a single genome codes for the information required to produce many different cell types, and to arrange these cells into specific tissues and organs that will eventually make up a complete organism. Strikingly, in humans this process is accomplished with only ~25 000 protein-coding genes, which is a relatively small number if one considers that the small mustard plant *Arabidopsis thaliana* has close to ~21 000 protein-coding genes. To amplify the information content of their seemingly limited genomes, higher eukaryotes have developed several mechanisms that allow them to generate the required biological complexity. Some of these include the genetic swapping of protein domains, posttranslational protein modifications, small RNA regulation, and alternative splicing.

Alternative splicing is the differential inclusion or exclusion of exons in a precursor messenger RNA transcript. Based on the number of genes impacted (~95% of humans genes), alternative splicing is one of the most extensively used mechanisms for generating proteomic diversity and cellular complexity. In this article, we describe the predominant classes of *cis*-acting sequences and RNA-binding proteins that regulate splicing decisions, and outline the basic mechanisms used by these splicing effector proteins to determine splicing patterns.

Splicing of Pre-Messenger RNAs

Most protein-coding genes in eukaryotes are composed of coding segments (exons) that are interspersed among noncoding sequence (introns) along the DNA. Both exons and introns are transcribed to produce a pre-mRNA, which is then spliced to remove intronic sequences and join exons to create a mature mRNA molecule (Figure 1). In a pre-mRNA the exon/intron boundaries are marked by specific, conserved sequences called splice sites (ss). These sequences are specifically recognized by the splicing machinery and direct the precise removal of introns and joining together of exons to produce a functional protein-coding transcript. The 5'-ss marks the exon/intron junction at the 5'-end of the intron and includes a conserved guanosine-uridine (GU) dinucleotide (Figure 1(a)). At the other end of the intron the 3'-ss has three conserved sequence

elements. The first element, going from 5' to 3' of the intron, is the branch point sequence (BPS), which contains a reactive adenosine that participates in the catalysis of splicing. The second element is a pyrimidine-rich sequence called the polypyrimidine tract (PPT) that is 10–40 nucleotides upstream of the third element, a conserved adenosine-guanosine (AG) dinucleotide at the extreme 3'-end of the intron (Figure 1(a)).

Bona fide splice sites must be recognized and paired from within a multitude of similar sequences in a given pre-mRNA molecule. This critical process is carried out by a highly specialized, RNA-based macromolecular enzyme known as the spliceosome. It is composed of five small nuclear RNP (snRNP) complexes (U1, U2, U4/U6, and U5), all of which consist of a uridine-rich snRNA (or two in the case of U4/U6) and multiple common and complex-specific proteins. Importantly, the spliceosome is not a preformed enzyme but instead forms through the assembly of the snRNP complexes on the pre-mRNA in a step-wise pathway that involves several intermediate complexes (E-, A-, B-, and C-complex; Figure 1(b)). The final catalytically active version of the spliceosome is ~1–2 MDa in size and consists of over 100 proteins. Although spliceosome assembly is commonly described as occurring across an intron, in higher eukaryotes where introns can be as many as hundreds of thousands of nucleotides long, spliceosome components are thought to first assemble across an exon (which are no more than ~50–250 nucleotides). However, cross-exon interactions must eventually transition into cross-intron interactions in order for catalysis to occur.

Types of Alternative Splicing Patterns

Although some exons in an RNA messenger transcript are constitutively spliced, that is, they are always included in the final message, the splicing of other exons is regulated (Figure 2). The most common type of regulated splicing event is what is called a cassette exon, which is an exon that is sometimes included and sometimes excluded from the mature mRNA. In some cases, cassette exons are mutually exclusive in which case only one exon from a group of two or more variants is selected. There are also instances where alternate 5' or 3' splice sites, located in tandem, can be used to

Figure 1 The spliceosome catalyzes the splicing of pre-mRNAs. (a) The exon and intron boundaries in a pre-mRNA are defined by conserved sequence elements: the 5' splice site, the BPS, a pyrimidine-rich track, and the 3' splice site. Y is a pyrimidine, R is a purine, and N is any nucleotide. (b) The stepwise assembly of the spliceosomal snRNPs (circles) during the removal of an intron from a pre-mRNA containing two exons (gray boxes) is shown. Assembly begins with the addition of the U1 snRNP to the 5'-ss and the U2AF (U2 snRNP auxiliary factor) to the BPS and PPT to yield the E complex. This is followed by the ATP-dependent binding of the U2 snRNP to the BPS, which displaces U2AF and leads to A complex formation. Subsequent recruitment of the U4/U6/U5 tri-snRNP results in the formation of a B complex. At this point, the snRNPs undergo extensive remodeling that results in the loss of the U1 and U4 snRNPs and the formation of catalytically active spliceosome (C complex).

produce different mRNA isoforms that differ in the length of a particular exon. By combining the use of alternative promoters and alternative splicing, the 5'-end of a transcript can be altered. Similarly, coordinate regulation of polyadenylation and splicing can alter the 3'-end of a transcript. Finally, in some cases the failure to remove a particular intron (i.e., intron retention event) in an mRNA can occur.

As shown in **Figure 2**, each of these altered splicing patterns has the potential to alter the coding sequence of the mRNA to give rise to a protein of distinct sequence and function. Frequently, individual protein domains are encoded by discrete exons, such that functionality can be determined by modular inclusion or exclusion of a particular domain-encoding exon. Alternatively, differential use of an exon, or inclusion of an intron may result in the introduction of a premature stop codon. In such cases, the mRNA or protein may be destabilized, such that alternative splicing becomes a mechanism to regulate the absolute level of protein expression. Finally, alternative splicing that changes the 5'- or 3'-UTR (UTR, untranslated region) of a message can determine the presence or absence of sequences that regulate message stability or translation. Thus, even changes in noncoding regions of an mRNA can ultimately control the expression or function of the resulting protein.

Auxiliary Sequence Elements and Proteins That Control Splice Site Recognition

In metazoan organisms, the majority of introns are large and contain many pseudo-splicing signals. Thus, pre-mRNA substrates usually contain additional regulatory sequence

elements that aid in the recognition and selection of legitimate splice sites and the repression of pseudo-splice sites. These *cis*-acting sequences are found in exons as well as in introns and can have positive or negative effects on spliceosome assembly. Sequence elements that activate splice-site usage and promote spliceosome assembly are called splicing enhancers. By contrast, sequences that block splice-site usage and inhibit assembly of the splicing machinery are described as splicing silencers. In a few cases, such regulatory sequences have been shown to act by inducing particular secondary structures in the pre-mRNA. However, the majority of regulatory sequences exert their effects by acting as binding sites for *trans*-acting protein factors, which in turn engage the snRNP subunits in a way that promotes or, in the case of negative regulators, inhibits assembly on neighboring splice sites (**Figure 3**).

Exonic splicing enhancers (ESEs) are often bound by members of the SR (serine-arginine) protein family. SR proteins are defined as containing one or more RNA recognition motif-type RNA-binding motifs at their N-terminus and a C-terminal domain that consists of Arg-Ser dipeptide repeats (RS domain) which interact with various components of the splicing machinery. ESEs are found within most constitutive exons in addition to many regulated exons. Therefore, SR protein binding to ESEs is essential for the selection and pairing of most genuine splice sites in both constitutive and alternative splicing. Splicing enhancers can also be located in introns (so-called intronic splicing enhancers or ISEs). ISEs do not act primarily through SR proteins, but rather serve as binding sites for a diverse array of RNA-binding proteins.

Splicing silencer sequences can similarly be located in either exons (exonic splicing silencer, ESS) or introns (intronic

Figure 2 Patterns of pre-mRNA alternative splicing. The most common patterns of alternative splicing are shown along with alternate products. Cases in which alternative promoter sites or alternative polyA sites are coupled with alternative splicing are indicated. Exons are depicted as boxes and introns as lines; dashed lines indicate the splice sites used in the splicing reaction. Constitutive exons are shown in gray and regulated exons are shown as light gray or black boxes.

splicing silencer, ISS). These negative regulatory elements are commonly recognized by members of the hnRNP family of RNA-binding proteins, a loosely defined family of structurally diverse RNA-binding proteins that share overlapping functions in RNA splicing, packaging, export, and stability. However, despite the above generalization that hnRNPs function as repressors and SR proteins function as activators of splicing, the activity of these two families of proteins, in some cases, depends on the location (exonic or intronic) of their binding site relative to the regulated exon. Other variables – such as the affinity of a protein for its binding site, its proximity to canonical splice sites, and the strength of the regulated splice sites – can also influence the exact function of a splicing regulatory

protein. For example, it has been demonstrated that hnRNP protein L (hnRNP L) represses exons flanked by strong splice sites but enhances those flanked by weak splice sites.

Mechanisms of Alternative Splicing Regulation

Fundamentally, alternative splicing occurs through the enhancing or silencing of exons or splice sites by modulating the assembly of the spliceosome on a pre-mRNA. Ultimately, the decision to include or exclude an exon into the final mRNA is based on the combination and/or integration of both the synergistic and antagonistic forces between groups of protein

Figure 3 *cis*-Acting regulatory elements and their cognate binding proteins control pre-mRNA splicing. Exonic and intronic splicing enhancer (ESE and ISE) elements are typically bound by SR proteins. SR proteins can promote and/or stabilize the interactions of the U1 snRNP to the 5'-ss and of the U2 snRNP to the 3'-ss across the exon or the intron. Also, ESE-bound SR proteins can recruit the U4/U6/U5 tri-snRNP. Exonic and intronic splicing silencers (ESSs and ISSs) are negative regulatory elements that are commonly recognized by hnRNP proteins. hnRNPs can occlude or antagonize the binding of the spliceosomal subunits to canonical splicing signals; also, binding of hnRNPs can antagonize the binding or the enhancing activity of SR proteins. Constitutive and alternative exons are depicted as black and gray boxes, respectively. Intronic regions (lines) are designated by the splice sites, where GU and AG marks the 5'-ss and 3'-ss, respectively, A is the branch site adenosine, and Yn is the polypyrimidine tract.

regulators and between protein regulators and the spliceosomal subunits. Such combinatorial regulation of splicing makes sense because the majority of the RNA–RNA, RNA–protein, and protein–protein interactions in the spliceosome are weak (i.e., low-binding affinity). Having these types of flexible intermolecular interactions enables the spliceosome to be highly responsive to regulation. The physiological significance of this flexibility is evident in the fact that lower eukaryotes such as budding yeast have much more precision in the RNA–RNA interactions that direct assembly of the spliceosome than is observed in metazoans, and correspondingly have little, if any, alternative splicing. Therefore, the inherent suboptimal nature of spliceosome assembly in metazoans allows for the richness of regulation that generates the diversity of protein expression required of complex organisms.

Both SR proteins and hnRNPs draw on a variety of strategies to direct the selection and pairing of specific splice sites and regulate splicing patterns (Figure 3). In the simplest case, the binding of hnRNPs to the pre-mRNA sterically blocks the interaction of spliceosomal subunits to an overlapping or adjacent splice site. hnRNP proteins can also function as silencers by competitively inhibiting the binding of an SR protein to a target exon. Conversely, in the best-characterized examples of SR protein function, the RS domain interacts with protein subunits of the splicing machinery so as to recruit or stabilize the binding of the spliceosome components to nearby splice sites.

In the simplest mechanisms described above, regulatory decisions occur during the early stages of spliceosome assembly (i.e., during the initial binding of the U1 and U2 snRNPs to the pre-mRNA, Figure 1). However, regulatory proteins such as SRs or hnRNPs can also influence later steps in spliceosome assembly (after the stabilization of U1 and U2 snRNP binding). Examples of such late assembly regulation include hyperstabilizing abortive intermediates, blocking of exon pairing, inhibition or enhancement of tri-snRNP (U4/5/6) recruitment, and even altering the location of RNA cleavage during catalysis (Figure 3). Indeed, as all steps in spliceosome assembly and catalysis involve molecular interactions and rearrangements, regulation of this process can potentially occur by manipulating the efficiency of any of these processes. It is also important to remember that virtually all pre-mRNAs contain multiple exons; therefore, there is inherent competition between flanking exons or splice sites. It follows then that strengthening or weakening a particular splice site, even marginally, can completely alter the composition of the final

mature mRNA by flipping the balance of splice site competition just enough to drive assembly down a favored pathway.

Additional Determinants That Contribute to Splicing Control

Splicing regulation does not simply lead to the static generation of multiple proteins from a single gene. More often than not, alternative exons are regulated in a cell-type- and developmental-stage-dependent manner, or, in some cases, their splicing is controlled in response to specific extracellular signals and signaling cascades. This allows cells to fine-tune protein expression in accordance with cell function and/or in response to changes in the extracellular environment.

Although SR and hnRNP proteins are ubiquitously expressed, there is some variability in the level of expression of individual family members across different cell types. As the balance of SR and hnRNP function often plays a key role in the relative activity of enhancer and silencer sequence elements, deviation in the relative expression levels of these proteins in a particular cell type can alter splicing patterns. A number of tissue- or developmental stage-specific hnRNP-like splicing regulators have also been identified in recent years. These include neuronal-specific proteins (e.g., Nova-1/2 and nPTB), muscle-enriched proteins (e.g., Fox, muscleblind-like (MBNL), and CUGBP and ETR3-like factor (CELF)), and the epithelial-specific proteins (e.g., ESRP-1/2). Such proteins have been shown to control the tissue-specific splicing and expression of large families of genes that are critical to the function of their respective cell types.

The activity of splicing regulatory proteins can also be regulated by posttranscriptional modifications. Signaling pathways including the MAP kinase cascade, growth factor signaling, neuronal depolarization, and many others have been shown to result in altered phosphorylation of various splicing factors. Changing phosphorylation status of SR or hnRNP proteins has, in turn, been demonstrated to alter activity and/or intracellular localization (e.g., nuclear vs. cytoplasmic localization) of these proteins and thus to alter the splicing of their target pre-mRNAs. Many hnRNP proteins are also predicted to undergo methylation, sumoylation, and acetylation among other possible posttranslational modifications. Such additional modifications of hnRNPs could potentially also influence their activity as splicing factors, although concrete examples of such are less well documented.

Finally, it is also worth noting that splicing patterns can be influenced by additional steps in mRNA biogenesis. Most notably, the splicing of alternative exons has been shown in some instances to be regulated by interactions between splicing factors and RNA polymerase II during active transcription. Variables such as changes in promoter activity, the presence or absence of a particular transcription factor, or the rate of transcriptional elongation can thus influence the pattern in which a gene is spliced.

Alternative Splicing of the CD45 Gene

An excellent model system to illustrate many of the mechanisms of alternative splicing described above, as well as the physiologic significance of this mode of regulation, is the human CD45 gene. CD45 encodes a tyrosine phosphatase protein that is expressed on the surface of lymphocyte cells and plays central roles in antigen receptor signal transduction and lymphocyte development and maturation. The function of the CD45 protein in these processes depends heavily on the regulation of the expression of its different splice variant mRNAs. In T cells, the three variable exons in CD45 (exons 4, 5, and 6) are partially repressed under quiescent or resting conditions, which gives rise to five different mRNA isoforms. When T cells encounter antigen and become activated, the three variable exons are hyper-repressed resulting in increased levels of the lower molecular weight isoform that lacks the three variable exons. Importantly, this switch in isoform expression upon cellular activation affects the enzymatic activity of the CD45 protein. The larger isoforms, which contain the

region encoded by the variable exons, exist predominantly as monomers and are catalytically active. In comparison, the smaller isoform, which lacks the variable exons, dimerizes more efficiently resulting in steric inhibition of the catalytic site.

The sequences and proteins that control CD45 splicing have been well studied and exemplify many of the concepts described in the sections above (Figure 4). The skipping of the three CD45 variable exons is mediated by a conserved ESS element that is located within each of the exons. Mutation or deletion of the ESS from each of the regulated exons abolishes exon skipping under both resting and stimulated conditions. For exons 4 and 6 the ESS motif is contiguous. By contrast, in exon 5 the ESS sequence is bisected by an ESE element (Figure 4(a)).

The protein hnRNP L is the primary ESS-binding protein in resting T cells and mediates the partial repression of each of the variable exons which is observed under resting conditions. Interestingly, though bound to a similar sequence in each exon, the mechanism by which hnRNP L functions to repress at least two of the CD45 exons is distinct (Figure 4(a)). The 3' splice site flanking CD45 exon 5 is particularly weak (poor match to consensus); thus, inclusion of this exon is completely dependent on the presence of the SR protein SF2/ASF bound to the ESE, which promotes association of the U2 snRNP. In exon 5, hnRNP L causes skipping by binding to the ESS in such a way that blocks the association of SF2/ASF with the intervening ESE, thereby preventing SR-dependent recruitment of the U2 snRNP. By contrast, in CD45 exon 4 the binding of hnRNP L to the ESS hyperstabilizes the already-efficient binding of the U1 and U2 snRNPs to the splice sites flanking the exon in such a way to inhibit their ability to participate in the cross-intron interactions necessary for catalysis.

Figure 4 Signal-induced alternative splicing of the CD45 variable exons. (a) In resting T cells, skipping of the three variable exons in CD45 (exons 4, 5, and 6) is mediated by the binding of hnRNP L to an exonic splicing silencer (ESS, gray box) embedded within each of the variable exons. hnRNP L represses exon 4 by hyperstabilizing the binding of the U1 and U2 snRNPs across the exon, thus preventing the cross-intron interactions necessary for catalysis. On exon 5, hnRNP L directly competes with SF2/ASF bound to an enhancer element (ESE, hatched box), inhibiting the ability of SF2/ASF to recruit the U2 snRNP to the upstream 3'-ss. Given the similar arrangement of the ESS in exons 4 and 6, we predict that mechanism of hnRNP L on exon 6 will likely mirror that of exon 4; however, this has not yet been confirmed experimentally. Constitutive CD45 exons are shown as black boxes. (b) Under resting conditions, PSF is phosphorylated at Thr 687 (T-P) and interacts with TRAP150. The interaction of PSF with TRAP150 prevents PSF from binding to the ESS in CD45 exons 4 and 5. Upon T-cell activation (Act.), the phosphorylation of PSF is reduced and it is now able to bind and further repress exons 4 and 5. Furthermore, expression of hnRNP LL is increased upon activation and participates in the repression of exon 4.

In response to T-cell activation, two proteins, hnRNP L-like (hnRNP LL) and the hnRNP-related protein PTB-associated splicing factor (PSF), are recruited to the ESS in CD45 exon 4 and function in combination with hnRNP L to achieve maximal exon repression. PSF also participates together with hnRNP L in the stimulation-induced exon silencing of CD45 exon 5; however, hnRNP LL has little to no effect on the regulation of CD45 exon 5 (**Figure 4(b)**). This differential protein involvement upon activation underscores the fact that small sequence variations between seemingly homologous regulatory elements can have profound consequences on the proteins through which they function. Therefore, sequence-based predictions of regulatory factors and mechanism should be viewed with caution.

The differential recruitment of hnRNP LL to exon 4 under resting and activated conditions is due, at least in part, to an increase in hnRNP LL protein levels upon stimulation, consistent with existence of cell-fate-specific regulatory factors as described above. Interestingly, however, the expression of PSF remains unchanged between resting and stimulated conditions. Instead, the recruitment of PSF to the CD45 pre-mRNA is controlled by the phosphorylation at a specific site in the protein. In resting cells, Thr 687 is phosphorylated which enhances the interaction of PSF with another protein called TRAP150. The interaction of TRAP150 with PSF prevents PSF from binding to the CD45 pre-mRNA (**Figure 4(b)**). Upon T-cell activation, the Thr687 phosphorylation of PSF is reduced and so the interaction of PSF with TRAP150 is also reduced. Unphosphorylated PSF is thus free to bind to the splicing regulatory elements in the CD45 pre-mRNA to repress variable exon inclusion. It should be noted, however, that precisely how the recruitment of PSF to exon 5, or PSF and hnRNP LL to exon 4, alters the mechanism of repression upon cellular stimulation is not entirely known.

The physiologic significance of CD45 alternative splicing is underscored by the fact that naturally occurring mutations in the human CD45 gene which disrupt splicing sequences have been implicated in the susceptibility to autoimmune diseases

and viral infections. One polymorphism in particular that disrupts the activity of ESS in exon 4 and results in increased inclusion of this exon is associated with susceptibility to the autoimmune disorder multiple sclerosis. In conclusion, CD45 is one of many examples of genes whose regulation at the level of splicing strongly determines the activity of the encoded protein and where splicing misregulation can cause disease. Therefore, understanding how alternative splicing can be controlled, and mapping the regulatory sequences and proteins that determine the splicing pattern of a particular gene, is essential for deciphering the precise expression of a protein and for predicting the consequence of genetic mutations.

Glossary

Polypyrimidine tract Pyrimidine-rich sequence near the 3' splice site.

Snf Fly homolog of the mammalian U1 and U2 snRNP proteins U1A and U2B''.

snRNP Protein–snRNA complexes.

U1-70K A protein component of the snRNP U1.

U2AF A splicing factor that recognizes the 3' polypyrimidine tract and is composed of two proteins, U2AF38 and U2AF50.

Alternative splicing provides a general mechanism for producing multiple products from a single gene that can have distinct biological activities. Alternative splicing can also be used to direct development by producing tissue-, stage-, or even sex-specific messenger RNAs (mRNAs). This is the case in *Drosophila* where the master-switch gene *Sex-lethal* (*Sxl*) uses sex-specific alternative splicing as a mechanism for remembering sexual identity, and for orchestrating sexual development. The use of alternative splicing for sex determination is not unique to the *Drosophilids*, but instead is widespread among insects. Interestingly, in some of the insect species that also use this mode of regulation for sex determination, the *transformer* gene, which plays a subordinate role to (*Sxl*) in *Drosophila* sex determination, functions as the master regulatory switch for memory and morphogenesis.

The Sex Determination Hierarchy in *Drosophila melanogaster*

Sexual Choice, Memory, and Differentiation

In *Drosophila*, the choice of sexual identity is made in early embryogenesis by the primary sex-determination signal, the X chromosome to autosome (X/A) ratio. The function of the chromosomal counting system is to set the activity state of the master regulatory switch gene *Sxl*. An X/A ratio of 1.0 specifies female identity by turning *Sxl* on, while an X/A ratio of 0.5 specifies male identity by keeping *Sxl* off (Figure 1). More recent studies on the transcriptional regulatory steps involved in the initial activation of *Sxl* argue that the process is more akin to an X chromosome counting system than a system that measures the X/A ratio. Once *Sxl* is activated, it maintains female identity through a positive autoregulatory feedback loop in which *Sxl* proteins promote their own expression. In addition to providing a mechanism for remembering the female determined state, *Sxl* orchestrates female development by directing the expression of several regulatory cascades in the female mode, and by sex-specifically modulating the activity of signaling pathways like *hedgehog* and *Notch*. In 1X/2A animals, male identity is remembered by the absence of *Sxl* protein, while male development is

specified by the default expression of these same regulatory cascades. While the initial choice of sexual identity is controlled at the level of transcription, many of the key regulatory steps for both memory and differentiation depend upon sex-specific alternative splicing and/or translational regulation.

Details of the Hierarchy

Although *Sxl* is on in females and off in males, it is transcribed in both sexes from a promoter, *Sxl-Pm*, which is active from the cellular blastoderm stage onward. The critical difference between the sexes is that all *Sxl* mRNAs in males have an additional exon, exon 3, which is spliced out in females (Figure 2(a)). This male-specific exon has multiple in-frame stop codons that prematurely truncate the *Sxl* open reading frame which begins upstream in exon 2. Consequently, male mRNAs do not encode functional proteins. By contrast, female *Sxl* mRNAs encode proteins that have two RNA recognition motif (RRM)-type RNA-binding domains. These proteins positively autoregulate their own synthesis by directing the splicing machinery to join exon 2 to exon 4, skipping the male-specific exon 3 (Figure 2(a)).

Since female splicing only occurs in the presence of *Sxl* protein, the X/A ratio must activate the *Sxl* autoregulatory feedback loop in female embryos by a mechanism that bypasses this requirement. This is accomplished by turning on a special promoter, *Sxl-Pe*, in pre-cellular blastoderm 2X/2A but not 1X/2A embryos. The *Sxl* proteins encoded by the *Sxl-Pe* mRNAs set the feedback loop in motion in 2X/2A embryos by directing the female-specific splicing of the first *Sxl-Pm* transcripts. Since *Sxl-Pe* is not activated in 1X/2A embryos, transcripts generated by *Sxl-Pm* are spliced in the default male pattern.

The primary regulatory target for *Sxl* in somatic sexual differentiation is *transformer* (*tra*). The second exon of the *tra* pre-mRNA has two 3' splice sites, the upstream default splice site and the downstream female-specific site (Figure 2(b)). *Sxl* turns *tra* on in females by promoting splicing to the downstream 3' splice site of exon 2. This generates mRNAs encoding functional proteins. When *Sxl* is absent, as in males, the default 3' splice site is used. Because there is an in-frame stop codon

Figure 1 Regulatory hierarchy in *Drosophila* sex determination: (a) female and (b) male.

just downstream of the default 3' splice site, male *tra* mRNAs encode truncated nonfunctional polypeptides.

Like *Sxl*, *tra* promotes female differentiation by regulating splicing. The two known targets, *double-sex* (*dsx*) and *fruitless* (*fru*), encode transcription factors. In the case of *dsx*, *tra* controls the production of sex-specific isoforms that have a common N-terminal DNA-binding domain, but different C-terminal activation domains. In females *Tra* promotes the joining of the 5' splice site of exon 3 to the 3' splice site of exon 4 (**Figure 2(d)**). In males, where *Tra* is absent, splicing is to the default 3' splice site of exon 5. While *Tra* regulates *dsx* splicing by controlling the use of alternative 3' splice sites, it regulates *fru* splicing by controlling alternative 5' splice sites. As illustrated in **Figure 2(e)**, the default upstream 5' splice site in exon 2 is used in males while the splicing machinery skips this 5' splice site in females using instead a 5' splice site located 1500 bp further downstream. Although both male and female mRNAs are predicted to encode proteins, the female-specific mRNA does not appear to be translated.

Figure 2 Exon organization and splicing patterns of alternatively spliced mRNAs encoded by *Drosophila* sex-determination genes: (a) *Sxl*; (b) *tra*; (c) *msl-2*; (d) *dsx*; and (e) *fru*. Female-specific splicing of *Sxl*, *tra*, and *msl-2* pre-mRNAs is regulated by *Sxl*, while female-specific splicing of *dsx* and *fru* is regulated by *Tra* and *Tra-2*.

Sxl also has *tra*-independent functions in female development. One of these is to downregulate *Notch*. This is thought to occur at the level of translation through *Sxl* binding to recognition sites in the untranslated regions (UTRs) of the *Notch* mRNA. Another is to augment *hedgehog* signaling. *Sxl* is found associated with cytoplasmic components of the *hedgehog* pathway and is thought to increase signaling by stabilizing the Cubitus interruptus transcription factor.

In addition to controlling somatic sexual differentiation, *Sxl* regulates dosage compensation. To equalize the dose of X-linked gene products in the two sexes, X chromosome transcription is upregulated in males by the MSL dosage compensation system. *Sxl* turns off the dosage compensation system in females by negatively regulating *msl-2* by blocking alternative splicing of an intron in the 5' UTR and by inhibiting the translation (Figure 2(c)).

Alternative Splicing Regulation by *Sxl*

tra: A Simple Blockage Model?

The regulation of *tra* splicing by *Sxl* involves a choice between alternative 3' splice sites (Figure 2). In principle, *Sxl* could promote the use of the downstream female-specific 3' splice site by preventing the splicing machinery from using the upstream default 3' splice site. Alternatively, it could activate the downstream 3' splice site. Sonsnowski et al. tested these models by deleting the alternative 3' splice sites. Deletion of the default 3' splice site led to use of the downstream female-specific 3' splice site not only in females, but also in males. This finding is inconsistent with a simple activation model since in this model *Sxl* would be required to promote the use of the downstream site even when the upstream site is missing. Deletion of the downstream 3' splice site did not interfere with splicing in males, but led to an increased amount of unspliced mRNA in females. This result is consistent with a simple blocking model because when the female-specific 3' splice site is absent, *Sxl* would still inhibit the use of the default 3' splice site, leading to an increase in unspliced mRNA.

Biochemical studies using a heterologous HeLa nuclear extract suggest that *Sxl* blocks the use of the default 3' splice site by competing with the generic splicing factor U2AF. U2AF binds to the polypyrimidine tract upstream of 3' splice site and facilitates spliceosome assembly by recruiting U2 small nuclear ribonucleoprotein (snRNP). Although mammalian U2AF recognizes both of the *tra* polypyrimidine tracts, it binds much more avidly to the default tract. The default tract is unusual in that it contains two canonical *Sxl*-binding sites, which are long poly U runs. Mutations in the *tra* poly U runs that eliminate *Sxl* binding *in vitro*, prevent *Sxl* regulation *in vivo*. Thus, the classic model for *tra* splicing is that the *Sxl* outcompetes U2AF for binding to the polypyrimidine tract of the default 3' splice site, forcing U2AF to bind to and activate the weaker, downstream 3' splice site.

Since a protein consisting of only the two *Sxl* RRM domains can bind to the default polypyrimidine tract with higher affinity than mammalian U2AF, this competition model predicts that only the RNA-binding domain of the *Sxl* should be necessary to direct female-specific splicing of *tra*. Indeed, this is the

case in *in vitro* splicing reactions. However, a *Sxl* protein that lacks the first 40 amino acids, but retains the RNA-binding domain is unable to regulate *tra* splicing *in vivo*. One explanation for this discrepancy is that *Sxl* binding of *Sxl* to the *tra* poly U runs must be stabilized *in vivo* by protein:protein interactions involving the N-terminal domain. However, this reasoning would not explain why a protein consisting of the N-terminal 100 amino acids of *Sxl* fused to β -galactosidase (N- β gal) is able to weakly promote female-specific splicing of *tra* when expressed in males. This N- β gal fusion protein does not have the two *Sxl* RNA-binding domains and consequently cannot directly compete with U2AF for binding to the polypyrimidine tract of the default 3' splice site. Taken together, these findings suggest that in addition to competing with U2AF for binding to the default polypyrimidine tract, *Sxl* may play a more active role in directing the splicing machinery to the downstream female-specific 3' splice site. As described below, *Sxl* is known to associate with a number of components of the splicing machinery *in vivo* including U2AF. Potentially such interactions could provide a mechanism for stabilizing U2AF binding to the female polypyrimidine tract and the consequent assembly of a functional spliceosome.

Sxl Autoregulation

Although *Sxl* autoregulation is also thought to involve a blockage mechanism, it is more complicated than *tra* because *Sxl* has to regulate the use of both the 3' and 5' splice sites of the male exon (Figure 2(a)). Like *tra*, the polypyrimidine tract at the 3' splice site of the *Sxl* male exon has a poly U run that is recognized by *Sxl*. However, since mutations in this poly U run have no effect on the splicing of *Sxl* pre-mRNAs in either tissue culture cells or transgenic animals, one can rule out a mechanism in which *Sxl* promotes female splicing by binding to the polypyrimidine tract of the male exon and occluding U2AF or other generic splicing factors.

In fact, splicing regulation *in vivo* does not seem to pivot on controlling the use of the male exon 3' splice site. When the male exon 5' splice site is deleted, placing the 3' splice sites of the male exon and exon 4 in direct competition, the male exon 3' splice site is skipped in *both* sexes and exon 2 is spliced exclusively to exon 4. A different result is obtained when the 5' splice sites of exon 2 and the male exon are placed in competition by deleting the male exon 3' splice site. In males, a new male exon is generated using a cryptic 3' splice site in the second intron and the normal male exon 5' splice site. Regulation of the deletion transcripts is also normal in females where *Sxl* directs the splicing of exon 2 to exon 4, skipping the cryptic male exon.

One mechanism for enhancing the role of the 5' splice site of the male exon is to weaken the male exon 3' splice site. The male exon is unusual in that it has two 3' splice site AGs, located 18 nucleotides apart, that compete with each other and reduce the efficiency of splicing. Utilization of the male exon in a heterologous context can be improved by mutating the upstream AG so that it can no longer be used. In the context of the regulated splice (exon 2-3-4), inactivating the upstream AG compromises the ability of *Sxl* to block the inclusion of the male exon presumably because the male exon 3' splice site now

functions much more efficiently. Lallena et al. have shown that the downstream AG is recognized by U2AF while the upstream AG is recognized by the splicing factor SPF45. As would be predicted if SPF45 is important for utilization of the upstream AG, reducing the activity of SPF45 in tissue culture cells or in flies substantially increases the utilization of the downstream 3' AG. The consequent improvement in efficiency of splicing of exon 2 to the male exon compromises the ability of Sxl to block the inclusion of the male exon.

How does Sxl regulate the male exon 3' and 5' splice sites? The critical targets for Sxl regulation are a series of poly U runs located about 200 bp away from the male exon in the upstream and downstream introns. Deletion of the upstream or downstream poly U runs greatly compromises but does not completely abolish regulation by Sxl, while regulation is eliminated when both are deleted. Since the critical poly U runs are distant from the regulated splice sites, it is thought Sxl exerts its effect on male exon splicing indirectly through interactions with other components of the splicing machinery. Consistent with this idea, a number of proteins have been found in complexes with Sxl, and mutations in the genes encoding these proteins show genetic interactions with Sxl. The best characterized of these is *sans-fille* (*snf*) which encodes the *Drosophila* homolog of the mammalian U1 and U2 snRNP proteins U1A and U2B'. Although recombinant Sxl and Snf interact directly with each other *in vitro*, the immunoprecipitable complexes between Snf and Sxl seen in nuclear extracts are RNase sensitive. Cline et al. proposed an snRNP-independent function for Snf in regulating Sxl splicing because they found that increasing the levels of *snf*, but not other genes encoding U1 or U2 snRNP proteins, could promote Sxl autoregulation under conditions of limiting Sxl protein. Supporting this idea, recent studies have shown that Snf can bind not only to the U1 and U2 small nuclear RNAs (snRNAs), but also to regions of the Sxl intron that have double poly U runs. However, this is probably not the whole story as genetic experiments by Nagengast et al. on mutants that specifically affect the association of Snf with the U1 and U2 snRNA show female lethal interactions with Sxl are observed for *snf* mutants defective in binding to the U1snRNP, but not the U2 snRNP. The same study also showed that Sxl can form an RNA-independent complex with the U1 snRNP protein U170K, and genetic interactions indicate that this protein:protein interaction is important for autoregulation.

The association of Sxl with two U1 snRNP proteins suggests that Sxl may prevent splicing between the male exon and exon 4 by blocking the assembly of a functional U1 pre-spliceosome complex at male exon 5' splice site. However, this would not explain how Sxl prevents exon 2 from splicing to the male exon 3' splice site(s). An understanding of the role of Sxl in this context is suggested from studies done with U2AF. In nuclear extracts, Sxl can form a complex with the U2AF proteins, U2AF50 and U2AF38, and Sxl mutations interact genetically with U2AF38. Nagengast et al. suggest that one mechanism Sxl might use to block splicing between exon 2 and the male exon would be through interactions with the U2AF heterodimer. Since U2AF recognizes the downstream AG in the male exon 3' splice site, some other mechanism might be required to block the use of the upstream AG. Since SPF45 is known to interact with U2AF, one possibility is that Sxl interaction with

U2AF at the downstream AG brings it into indirect contact with SPF45 at the upstream AG.

Genetic and molecular studies indicate that genes encoding other splicing factors play an important role in Sxl splicing regulation. One of these is *female lethal on the 2nd*, (*fl(2)d*). *fl(2)d* is homologous to the human spliceosomal *wilm's tumor associated protein* (*wtap*). Like other factors critical for Sxl splicing, *fl(2)d* shows synergistic female lethal interactions with mutations in Sxl, *snf*, and U2AF. For *snf*, *fl(2)d* showed genetic interactions not only with the *snf* mutant defective in U1 snRNP association, but also with the mutation defective in U2 association. Consistent with these genetic interactions Penn et al. found that like Snf, Fl(2)d interacts directly with Sxl protein *in vitro*, while in nuclear extracts Fl(2)d is in complexes with Sxl, Snf, U2AF50, U2AF38, and U1-70K. With the exception of Snf bound to U2 snRNP, all of these proteins are associated with spliceosomal complexes that are present at early steps in the splicing reaction prior to the first transesterification reaction. By contrast, complexes between Fl(2)d and proteins present like the U5 snRNP protein U5-40K and SKIP that are present later in the splicing reaction after the association of the U4/U6,U5 tri-snRNP with the spliceosome are not detected. Likewise, while Sxl was associated with U2AF⁵⁰, U2AF³⁸, and U1-70K, it was not found in complexes with either U5-40K or SKIP.

Taken together these findings would argue that splicing regulation by Sxl takes place at an early step in the splicing pathway, most likely prior to the first transesterification reaction. This idea is supported by studies on a Snf-interacting protein partner of Snf (PPS). As would be expected for splicing factors involved in Sxl autoregulation, mutations in *pps* shows female lethal interactions with Sxl and with other known splicing factors such as *fl(2)d* and U2AF38. In addition, PPS is found in complexes with the U1 snRNP, Sxl, and unspliced Sxl RNAs. However, PPS does not seem to be a typical splicing factor. Rather it seems to be a component of the transcriptional apparatus, perhaps functioning to coordinate transcription with alternative splicing. Rather it seems to be a component of the transcriptional apparatus, perhaps functioning to coordinate transcription with alternative splicing. Consistent with this hypothesis, recent studies have shown that the coupling between transcription and splicing of the regulated splice (exons 2–4: [Figure 2\(a\)](#)) in Sxl pre-mRNAs differs in males and females. Splicing of constitutively spliced exons typically occurs as the pre-mRNA is being transcribed and is completed before the RNA is released and polyadenylated. This is what is observed for Sxl pre-mRNA splicing in males – the regulated splice (exon2–exon3–exon4) is processed co-transcriptionally just like the constitutively spliced exons elsewhere in the Sxl pre-mRNA. In females, splicing of the constitutively spliced exons is also co-transcriptional; however, the splicing of the regulated splice (exon2–exon4: [Figure 2\(a\)](#)) is uncoupled from transcription and does not take place until after the transcript has been released from the Sxl locus. This uncoupling of transcription and splicing when pre-mRNAs are spliced in an alternative or regulated pattern rather than in the default pattern appears to be a general phenomenon. Moreover, in the case of Sxl it would explain why translation factors such as eIF4E and PABP have implicated in helping Sxl direct the female-specific splicing of Sxl and also *msl-2* pre-mRNAs.

Figure 3 Splicing factors recognize splicing signals differently in females and males. (a) In this model for *Sxl* autoregulation, *Sxl* prevents inclusion of the male exon in the spliced mRNA in females by sequestering splicing complexes associated with the male exon splice sites. (b) In this model for *tra* regulation, *Sxl* blocks the association of U2AF with the default 3' splice site, forcing it to associate with the female 3' splicing site. (c) Tra (purple), Tra-2 (yellow), SR proteins (tan), and Rbp1 bind to sites in the female-specific *dsx* exon, recruiting U2AF to the female 3' splice site.

Alternative Splicing Regulation by Tra

Tra Protein

Tra is an arginine/serine domain containing splicing regulator (SR) protein. SR proteins generally function to activate splice sites, but there are examples of SR proteins that are able to block splice sites instead. In *Drosophila*, female-specific Tra functions with sex-nonspecific Tra-2 to activate splice sites in *dsx* and *fru* pre-mRNAs.

Regulation of *dsx* and *fru*

In males, the default splicing machinery joins the 5' splice site of *dsx* exon 3 to the 3' splice site of exon 5. When Tra is present in females it promotes splicing of exon 3 to exon 4 by activating the 3' splice site of exon 4. Exon 4 contains six 13-nucleotide repeat elements (REs) and one purine rich element (PRE) (located between RE #5 and RE #6) that are necessary for efficient use of the female-specific splice site. When these elements are deleted, *dsx* is spliced in the male pattern irrespective of whether Tra is present. Conversely, when these elements are placed downstream of a heterologous 3' splice site they can activate the splice site when Tra is present. *In vitro* experiments indicate that Tra and Tra-2, together with

the SR protein Rbp1 associate with the 13-nucleotide REs, while the SR proteins dSRp30 and b52/dSRp55 function at the PRE. It is thought Tra and Tra-2 plus the various SR proteins form an enhancer complex in exon 4. Since Tra and Tra-2 interact with U2AF38, this suggests a model in which the enhancer complexes assembled in exon 4 recruit U2AF38 and subsequently U2AF50 to the 3' splice site.

This model is complicated by the fact that the *fru* transcript contains three similar Tra/Tra-2 binding sites within exon 2, which are necessary for activating a female-specific 5' splice site. This is difficult to reconcile with the U2AF recruitment model because recruiting U2AF is not useful for activating a 5' splice site. Moreover, when the six REs and the PRE within exon 4 of *dsx* are replaced with the Tra/Tra-2 binding sites found in the *fru* transcript, activation of the female-specific 3' splice site still occurs. One explanation for this result is that recruitment of general splicing regulators by Tra, Tra-2, and other SR proteins might be context dependent. Which component of the splicing machinery is recruited may be determined by additional proteins specific to each transcript that bind to sites other than the REs and/or PREs.

In addition to functioning as a cofactor in female-specific *dsx* and *fru* splicing, *tra-2* is required in male testes for normal spermatogenesis. Interestingly, there are testes-specific *tra-2* mRNAs in which the splicing of one of the introns, M1, is

blocked by the Tra-2 protein. This results in the production of a nonfunctional *tra-2* mRNA. Recent studies by Qi et al. have shown that Tra-2 together with the Rbp1 protein interacts with recognition sequences in the M1 intron to block splicing. This contrasts with the activation of splicing by Tra-2 and Rbp1 seen for *dsx*. Tra-2 is normally expressed at very high levels in the testes compared to other tissues, and it appears that this negative autoregulatory activity of Tra-2 provides a mechanism for preventing further accumulation.

Alternative Splicing and Sex Determination in Other Species

Sex-lethal is produced in a sex-specific manner within the genus *Drosophila* but in every other dipteran examined outside of this genus, *Sex-lethal* is not expressed sex specifically, nor does it appear to have a role in sex determination. By contrast, the downstream genes seem to have maintained their role in sex determination. At the bottom of the *Drosophila* sex-determination hierarchy is *dsx*. This gene is widely distributed in the animal kingdom and in insects is differentially spliced in males and females. As in the *Drosophilids*, the default *dsx* splicing pattern is male in the Queensland fruit fly, the Phorid fly, and the housefly, while the female pattern is orchestrated by Tra and Tra-2 through target sequences for these factors in the female-specific exon. While the splicing of *dsx* mRNAs is also sex-specifically regulated in *Bombxy*, the default pattern is female and not male, and splicing regulation does not depend upon either Tra or Tra-2. Instead, it appears to be mediated by a KH domain protein, P-element somatic inhibitor (PSI) protein, which binds to sites in one of the female-specific exons and blocks the inclusion of the exon in male mRNAs.

In insects that have *tra* and *tra-2* but not *Sxl*, the *tra* gene seems to act as the master regulator of sex determination. This was first shown for *Ceratitidis Capitata tra*. *Cetra* is the target for initial sex-determination signal and once activated it not only directs the female splicing of *dsx*, but also maintains its own expression by promoting the female splicing of its own mRNAs. Similar findings have been reported for the housefly, *Musca*. *Mdtra* and *Mdtra2* are required for the female-specific splicing of *Mdtra* mRNAs and ectopic expression of a female *Mdtra* mRNA is sufficient to induce female splicing of message from the endogenous *Mdtra* gene. As in *Drosophila*, the male and female *Cetra* and *Mdtra2* differ by the presence or absence, respectively, of a translation termination signal in male-specific exon sequences just downstream of the translation start site.

However, the splicing patterns that generate the male- and female-specific exon sequence are complex and in the case of the housefly it is argued that male splicing is also likely to require male-specific factors and these male factors may be relevant to the mechanism of pathway choice.

Summary

Drosophila sex determination is a powerful and practical system in which to examine the mechanisms of alternative splicing and within the sex-determination hierarchy are examples of different mechanisms for regulating alternative splicing. *Sxl* autoregulation is controlled by blocking the 3' and 5' splice sites of an exon, while female-specific *tra* expression is achieved by blocking the stronger 3' splice site (Figure 3). Splice site activation is used for female-specific *dsx* and *fru* expression. However, a 3' splice site is activated in *dsx* whereas a 5' splice site is activated in *fru*. Each of the different alternative splicing events are unique, but some of the proteins regulating these splicing reactions are shared.

Glossary

Amines Hydrocarbon compounds bearing an amine group. They are called primary, secondary, or tertiary when nitrogen binds two, one, or zero hydrogen atoms.

Oxidases Enzymes that oxidize substrates using molecular oxygen.

Polyamines Hydrocarbon compounds bearing both primary and secondary amino groups

(e.g., spermine and spermidine) strongly interacting with nucleic acids involved in many important cellular functions.

Primary amines Metabolically derived from amino acids by decarboxylation. Primary amines often show potent pharmacological or hormonal activity (e.g., histamine, serotonin, GABA, and noradrenaline).

Classification

The oxidative deamination of mono-, di-, and polyamines is catalyzed by a number of enzymes called 'amine oxidases' (AOs) that exhibit different patterns of substrate specificity and inhibitor sensitivity and also differ in their action mechanism. AOs are divided into two main categories, depending on the nature of the cofactor involved. Monoamine oxidases (MAOs) and polyamine oxidases (PAOs) belong to the first class and utilize flavin adenine dinucleotide (FAD) as the redox cofactor (**Figure 1(a)**). The second class is represented by enzymes having a tightly bound Cu^{II} ion and a carbonyl-type moiety identified as 6-hydroxydopa quinone (2,4,5-trihydroxyphenethylamine quinone; TPQ or TOPA) at the active site (**Figure 1(b)**).

Distribution, Reaction Mechanism, and Physiological Roles

Monoamine Oxidases

Two forms of MAOs (MAOs, amine: oxygen oxidoreductase (deaminating, flavin-containing); EC 1.4.3.4) have been described, namely MAO A and MAO B, the former made by 527 amino acid residues and the latter by 520, with an overall 70% identity. Both enzymes have a FAD covalently bound through its C8 α -position to a cysteine (Cys406 in MAO A and Cys397 in MAO B) side chain (**Figure 1(a)**). Both forms of MAOs have been crystallized from many different sources.

MAOs are ubiquitous in cells of most mammalian species, the notable exception being erythrocytes, and are tightly associated with the mitochondrial outer membrane. The distribution of MAOs has been mainly studied in brain: MAO A is found in catecholaminergic neurons, whereas MAO B is abundant in serotonergic and histaminergic neurons and glial cells. Some tissues mainly contain MAO A (human placenta and bovine thyroid), while other tissues contain predominantly MAO B (human platelets and bovine liver and kidney).

MAOs oxidize primary amino groups of arylalkyl amines to form an imine intermediate with the concomitant reduction of flavin to FADH_2 . The imine is then hydrolyzed to the

corresponding aldehyde and ammonia, and FADH_2 is oxidized back to FAD by oxygen with the formation of hydrogen peroxide. MAO A oxidizes dopamine, noradrenaline, and serotonin whereas MAO B preferentially oxidizes benzylamine and phenylethylamine. Adrenaline, kynuramine, tyramine, and tryptamine are substrates for both enzymes.

MAO A and B have been implicated in apoptosis, immunosuppression, cytotoxicity, cell growth, and proliferation. These enzymes play a protective role in the body by preventing the entry of amines at renal and intestinal level or by oxidizing them in blood. Liver MAOs are important for the control of blood pressure by regulating the amines level. For instance, MAO A can oxidize circulating serotonin thus preventing its effects on heart and vascular system. Both enzymes have important roles in the metabolism of neurotransmitters and other biogenic amines in the brain and are implicated in a large number of neurological and psychiatric disorders. As a matter of fact, MAO A inhibitors are used as antidepressants whereas MAO B inhibitors have an important role in the treatment of Parkinson's disease.

A further important role of MAOs is recently emerging, that is, their role in the demethylation of histone lysines and arginines, an essential process in the regulation of gene expression and genomic imprinting.

Polyamine Oxidases

PAOs (N^1 -acetylspermidine:oxidoreductase (deaminating); EC 1.5.3.11) have been classified as part of flavoprotein superfamily but in this case FAD is noncovalently bound to the protein. PAOs are monomeric enzymes with a molecular mass ranging from 53 kDa to 63 kDa. PAOs are found in vertebrates and plants. Enzymes with characteristics similar to those of vertebrates' enzymes are present in yeasts and amoebae, whereas bacteria and protozoans contain enzymes resembling those of plants. Plant PAOs have been isolated and characterized, particularly from the Gramineae oat, maize, barley, wheat, and rye. The enzyme from maize seedlings has been crystallized.

Much alike the catalytic mechanism of MAOs, the oxidation of polyamines can be divided into two half-reactions: (1) flavin

reduction upon polyamine oxidation followed by (2) flavin reoxidation by molecular oxygen. PAOs catalyze the oxidation of polyamines' secondary amino groups yielding different products depending on the organism considered. Mammalian

Figure 1 Structure of the (a) FAD covalently bound in MAOs; (b) the oxidized form of TPQ; and (c) lysyl tyrosylquinone.

PAOs preferentially oxidize acetyl spermine and acetyl spermidine: spermidine and putrescine are the respective reaction products, together with 3-aminopropanal and hydrogen peroxide. Oxidation of spermine by plant PAOs gives 1,3-diaminopropane, hydrogen peroxide, and 1-(3-aminopropyl)-4-aminobutanal. The latter spontaneously cyclizes to 1-(3-aminopropyl)pyrrolinium that undergoes further spontaneous rearrangement to 1,5-diazobicyclo[4.3.0.]nonane (**Scheme 1**). The oxidation of spermidine by plant PAOs gives 1,3-diaminopropane, hydrogen peroxide, and 4-aminobutanal that yields 1-pyrroline by spontaneous cyclization. At variance with MAOs and copper/topaquinone (TPQ) AOs, the oxidation of polyamines by PAOs does not release ammonia.

PAOs play an important role in the regulation of intracellular polyamines level, and seem to be important for homeostasis and cell survival.

Copper Amine Oxidases

Copper amine oxidases (amine: oxygen oxidoreductase (deaminating; copper containing); EC 1.4.3.6) (CAOs) are homodimers in which each subunit (M_w 70–90 kDa) contains a tightly bound type II copper ion and a TPQ. TPQ is derived from a posttranslational modification of a tyrosyl residue, found in a strictly conserved amino acid consensus sequence asn-tyr-asg/glu (NYD/E). The pink color of CAOs stems from an intense absorption band around 500 nm due to the oxidized TPQ. CAOs catalyze the oxidative deamination of primary amino groups of mono-, di-, and polyamines, abstracting two electrons from amines and transferring them to molecular oxygen, to form the corresponding aldehyde, ammonia, and

hydrogen peroxide. Again, the catalytic mechanism can be divided into two half-reactions: (1) enzyme reduction at the quinone moiety ($\text{TPQ} \rightarrow \text{TPQH}_2$) by substrate followed by (2) reoxidation by molecular oxygen

The group of CAOs includes the following:

1. Diamine oxidases (DAOs), ubiquitous enzymes occurring in prokaryotes as well as eukaryotes (bacteria, fungi, plants, and animals). Several DAOs have been crystallized from bacteria, from the yeast *Hansenula polymorpha*, and from pea seedlings. Plant DAOs from various species have been purified to homogeneity and characterized, the best known and studied being those from lentil (*Lens esculenta*) and pea (*Pisum sativum*) and from latex of the shrub *Euphorbia characias*. In mammals, the best-known enzymes are those from pig kidney and intestine and human placenta. DAOs are mainly active on short aliphatic diamines, such as putrescine (1,4 diaminobutane) and cadaverine (1,5 diaminopentane).

The physiological role of DAOs is multifaceted, because this class includes several enzymes with different localizations and substrates. Bacteria and yeasts can utilize amines as nitrogen and carbon sources through the reaction with AO. Plant DAOs are implicated in wound healing, in detoxification, and in cell growth by regulating the intracellular di- and polyamine levels, and the aldehyde products might have a key role in the biosynthesis of some alkaloids. The function of DAOs in mammals is even more diverse and elusive and a plethora of physiological functions, sometimes opposite, have been described. AO activity is found in many tissues, the highest levels being in decidual cells of placenta, in kidney tubular epithelial cells, and in intestinal epithelial cells. These localizations may suggest a barrier function for DAOs to prevent the entry of diamines and polyamines in the body. Furthermore, these enzymes may keep at bay the endogenous histamine, which otherwise can cause several pathological conditions such as allergy, peptic ulcer, and anaphylactic reactions. Several observations point to a relationship between AO activity and growth, both in normal and tumor tissues, that is, in cell proliferation and differentiation. DAOs have also been proposed as immune response modulators. It has been demonstrated that human placental DAO is identical to the amiloride-binding protein and thus in some way involved in the regulation of epithelial ion transport. In analogy with MAOs, also DAOs have been proposed to be involved in demethylation of histones, in particular of methylated arginines. In this case, their importance might be not only the modification of histones but also the production of hydrogen peroxide just at nuclear level.

2. The mammalian extracellular soluble and intracellular tissue-bound AOs are able to metabolize mono-, di-, and polyamines, even though *in vitro* they are preferentially active toward nonphysiological amines such as benzylamine. Extracellular AOs are generally called either plasma and serum AOs or benzylamine oxidases (BzAOs). The better-known BzAOs are those from bovine, swine, and equine plasma.

The enzyme from bovine plasma has been crystallized. Tissue-bound AOs are often indicated somewhat misleadingly as semicarbazide-sensitive amine oxidases (SSAOs), since all CAOs, at variance with FAD-dependent enzymes, are inhibited by semicarbazide and other carbonyl reagents. Intracellular SSAOs are widely distributed: smooth muscle cells of vascular tissue of all mammalian species are good sources of these enzymes, which have been also detected in uterus, ureter and vas deferens, in ox dental pulp, in human umbilical artery, in rat adipocytes, and chondrocytes.

Plasma AOs may be considered key enzymes in cell growth and differentiation processes and, thus, in tumor development and growth regulation. Moreover, the increased BzAO activity in blood serum of pregnant women supports the possibility that this enzyme has a protective role against the polyamines released from the fetoplacental unit. SSAOs seem to play an important role in vascular wall. Moreover, these enzymes might be involved in the regulation of glucose metabolism (perhaps via the H_2O_2 produced) and in the regulation of leukocyte trafficking in endothelial cells. SSAOs have also been shown to be a new class of DNA-binding proteins: in the presence of polyamines, they bind DNA and oxidize DNA-bound polyamines. A structural similarity between SSAOs and VAP-1, a protein involved in cellular adhesion, has been observed and a human SSAO/VAP-1 protein has been crystallized.

3. The mammalian extracellular matrix-bound lysyl oxidase [EC 1.4.3.13] (LOX), a 30-kDa protein, differs from other members of the group because a lysyl tyrosyl quinone (LTQ) rather than TPQ is the redox cofactor (Figure 1(c)). LTQ is formed by oxidation of a conserved tyrosine residue and subsequent intramolecular cross-linking with the ϵ -amino group of a conserved lysine. LOX catalyzes the oxidative deamination of lysyl residues in elastin and collagen allowing the formation of cross-links essential for the structure of these proteins. The genetic or acquired decrease of LOX activity is accompanied by severe pathological conditions such as tendon laxity and formation of aneurisms in arteries.

A LOX from *Pichia pastoris* has been crystallized and characterized. This enzyme, cloned and overexpressed, shows TPQ as the redox cofactor. *Pichia pastoris* LOX displays catalytic activity toward tropoelastin (the un-cross-linked form of elastin), and lysine and lysine-containing peptides are the preferred substrates for this enzyme. In this respect, it resembles the LTQ-containing mammalian AOs.

Concluding Remarks

In the past few years, evidence has accumulated about the physiological relevance of hydrogen peroxide, which is generated in the catabolism of mono-, di-, and polyamines by all AOs. Hydrogen peroxide, which is always formed in the reactions catalyzed by AOs, is more and more considered either a crucial reagent for important biochemical processes or a signal and a defense molecule, rather than a noxious waste product.

This reactive oxygen species is toxic at high concentration. However, at lower concentrations it regulates the cell number

during embryonic development as well as the proliferation and adhesive properties of endothelial and smooth muscle cells. Hydrogen peroxide appears to be involved in the impairment of cell growth and proliferation, in the regulation of many genes and transcription factors, and in the transduction of cellular signals in many living species. In plants, hydrogen peroxide might be utilized by peroxidases in basic physiological events, such as development, polymerization of lignin and suberin precursors, and catabolism of indoleacetic acid, in response to wounding or to pathogen invasion.

Amino Acid Metabolism

L Cynober, Paris Descartes University, Paris, France

© 2013 Elsevier Inc. All rights reserved.

Glossary

Ammoniogenesis *De novo* ammonia synthesis from amino acids. The main precursor is glutamine and this process occurs mainly in the kidney. Ammoniogenesis plays a key role in acid–base homeostasis.

Enterocyte A cell that ensures the transport of nutrients from the gut lumen to the bloodstream and protects the internal milieu from invasion by bacteria and others.

Essential amino acid An amino acid that cannot be synthesized by humans; hence, their provision is strictly dependent upon alimentation.

Gluconeogenesis Glucose synthesis from nonglucidic precursors. Main substrates are amino acids (AAs, mainly

alanine, glutamine, and proline), lactate, pyruvate, and glycerol. Gluconeogenesis occurs during fasting mainly in the liver and also in the kidney.

Ketogenesis Synthesis of ketone bodies. Fatty acids are the main substrates. Some AAs are also involved, especially leucine. Ketogenesis occurs specifically in the liver.

Ureagenesis Synthesis of urea from ammonia or from ammonia derived from amino acids. This allows removal of amino acid in excess and/or the incorporation of the carbon moiety of AAs into glucose (i.e., gluconeogenesis). Ureagenesis is located in the liver.

Structure, Functions, and Classification of Amino Acids

Amino acids (AAs) are defined as organic molecules possessing an amino moiety located at α -position to a carboxylic group. AAs therefore have the following general formula:

where R may be an aliphatic or a cyclic structure.

Note that proline (PRO) is considered as an AA even though its $-\text{NH}_2$ group is part of a heterocycle. Also, taurine is considered as an AA even though it has a sulfur moiety instead of an amino group in the α -position.

AAs can be classified in three different ways (Table 1):

Chemical classification. This classification is based on structure and identifies different chemical families of AAs: aliphatic (subdivided into several subgroups – see Table 1 for details), aromatic, heterocyclic, etc.

Metabolic classification. Although in theory most AAs can be precursors of glucose, *in vivo*, because most AAs preferentially use other metabolic pathways, only alanine (ALA), glutamine (GLN), and, to a lesser extent, PRO and glycine (GLY) contribute significantly to gluconeogenesis.

Only AAs engaged in protein bonds are presented. Note that there are numerous other AAs: (1) intermediary metabolites (ornithine, citrulline (CIT)) and (2) post-transcriptionally formed (hydroxyproline, γ -carboxyGLU acid) (a) in italics: essential AAs; (b) in bold type: gluconeogenic AAs; and (c) underlined: ketogenic AAs.

Certain AAs can be precursors of ketone bodies (ketogenic AAs). Again, *in vivo*, only leucine (LEU) contributes significantly to ketogenesis.

Finally, some AAs can be both glucogenic and ketogenic: isoleucine (ILE) and phenylalanine (PHE).

Nutritional classification. This is based on what AAs the human body can or cannot synthesize. The former are

named nonessential AAs (NEAAs) and the latter essential AAs (EAAs). There are nine EAAs (Table 1). Note that some NEAAs can become EAAs in specific situations where synthesis does not match requirements (e.g., arginine (ARG) during growth, tyrosine (TYR) during renal failure, or GLN in trauma patients).

General Reaction of AA Metabolism

There is a considerable number of metabolic reactions involving AAs. The general reactions (i.d. concerning a significant number of AAs) relate to the (1) amino group(s), (2) the carboxylic group, and (3) the carbon structure.

Reactions Involving the Amino Group

Transamination reaction

This is a quite general reaction, present in all tissues. This is both a synthesis and a catabolic reaction since it is the reversible transfer of an amino group from an AA (AAR1) (becoming a keto acid) to a keto acid (becoming an AAR2):

It should be noted that, for one given AA, a transamination reaction may be a synthesis way in one organ (e.g., ALA in muscles) and a catabolic way in another (e.g., ALA in the liver).

The transamination enzymes possess a prosthetic group: pyridoxal phosphate which binds the AA during the reaction. So the reaction follows a ping-pong-type mechanism:

Table 1 Classifications of amino acids

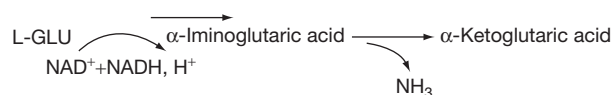

<i>Aliphatic</i>	<i>Aromatic</i>	<i>Dibasic</i>	<i>Diacid</i>	<i>Heterocyclic</i>	<i>Imino acid</i>
● Short-chain Glycine Alanine ● Alcohol Threonine Serine ● Branched-chain Leucine Isoleucine Valine ● Sulfur Methionine Cysteine	Phenylalanine Tyrosine	Arginine Histidine Lysine	Glutamate Glutamine Aspartate Asparagine	Tryptophan	Proline

where A–X and B–X are AAs, A and B are keto acids, and X is an amino group.

Oxidative deamination

The best example of oxidative deamination is the L-glutamate dehydrogenase.

The direction in this reaction depends on the rate of use of the product of the reaction:

- degradation of GLU into the intestine (to fuel the Krebs cycle) and in the kidney (for ammoniogenesis) and
- synthesis of GLU into perivenous hepatocytes (for resynthesis of GLN).

Decarboxylation Reactions

These reactions generate amines:

the most important ones include putrescine (from ornithine (ORN)), histamine (from histidine (HIS)), and tyramine (from TYR).

Metabolism of the Carbon Skeleton

The metabolism is specific for each AA but metabolites converge toward a limited number of end products (e.g., intermediary of the Krebs cycle, glucose, and ketone bodies).

Intestinal Absorption of AAs

Digestion of proteins (beyond the scope of this article) releases a mixture of free AAs and short-chain peptides. Nitrogen is absorbed mainly in the jejunum and the ileum in the form of

free AAs and di- and tripeptides. It is now well recognized that the latter have a kinetic advantage for uptake. To date, two peptide transporters have been cloned, PEPT-1 and PEPT-2.

AAs are taken up by systems that are rather different from those found in other cells and also from those located at the basolateral side of enterocytes. The groups of transporters are relatively specific to:

- neutral AAs,
- imino acids,
- dibasic AAs + cysteine (CYS), and
- dicarboxylic AAs.

Intestinal Metabolism

It was long thought that the gut had a single function, namely, taking up AAs from the lumen for transport in the bloodstream.

In fact, the intestine avidly consumes some AAs for its energy requirements: GLU and GLN are used to the same extent as glucose by enterocytes, producing α-ketoglutarate, which is oxidized in the Krebs cycle. After a balanced meal, at least 30% of GLU + GLN is used by enterocytes, and as a consequence ammonia is released in the portal vein. Interestingly, when GLN is taken up at the luminal side of enterocytes, its uptake at the basolateral side decreases. The reverse is true in the post-absorptive state, so that the supply of GLN to enterocytes remains roughly constant.

Also, the turnover of enterocytes is very rapid, causing a strong requirement for purine and pyrimidine precursors (e.g., GLN).

Cellular Transport of AAs

Once AAs appear in the circulation, cellular transport is a critical step in AA metabolism, since it is a prerequisite for any further metabolism. In certain cases this step may even be rate limiting or rate controlling for metabolic pathways.

The systems of transport have long been classified according to their preferred substrates, their dependency toward sodium, their sensitivity to pH, and their ability to transport nonmetabolizable analogs. Based on these criteria, a large number of transport systems have been identified. The most

ubiquitous systems are system A (A for ALA-preferring), system ASC (ALA-, serine (SER-) and CYS-preferring), system L (LEU-preferring), γ + (ARG being the main substrate), N (for the transport of GLN and HIS), etc. With progress in molecular biology methods, a number of transporters have been cloned, allowing a new classification. Not surprisingly, the number of transport systems was found to be greater. For example, for ARG, four transporters have been cloned (CAT-1, CAT-2A, CAT-2B, and CAT-3) with different cell localizations, properties, and affinities for the different cationic AAs. The organs that contribute most to AA metabolism are the liver and muscle.

Liver Metabolism

The liver holds a central place in the metabolism of AAs because it is responsible for the synthesis of most circulating proteins, transforms AAs as energy sources (i.e., glucose and ketone bodies) for other tissues, and eliminates surplus nitrogen.

AAs supplied via the portal vein after a meal are heavily metabolized (50%). The carbon chain is oxidized or forms glucose, which is saved as glycogen, while the N-moiety (ies) is (are) removed in ureagenesis.

The reason for this process is that whereas the intestinal absorption of AAs is not limiting (95–99% of nitrogen is absorbed in a large range of protein intake), the brain must be protected against excessive AA exposure because several of them are neurotoxic or are the precursors of potent neuromediators (see Table 2). Thus, the liver acts as a filter, limiting the amount of AAs released in the general circulation. Notable exceptions are the branched-chain AAs (BCAAs; valine (VAL), ILE, LEU), which are almost nonmetabolized in the liver: BCAAs form 22% of AAs in food proteins but almost 50% of AAs reaching the general circulation.

The biochemical explanation for this effect is that hepatocytes do not contain BCAA transaminase (BCAA-T), which mediates the first step of BCAA metabolism. The physiological reason may be related to the fact that LEU plays a critical role in the stimulation of muscle protein synthesis in the post-prandial phase.

In the post-absorptive state, with glycogen exhaustion, gluconeogenesis increases to maintain glucose homeostasis. As stated above, ALA is the main gluconeogenic substrate among AAs: in healthy humans starved for 8 h, 30% of perfused ALA is metabolized into glucose, and, in these conditions, 11%

of glucose formed by the liver comes from ALA. When the starvation time is increased, and in situations of hyperglucagonemia (e.g., during response to injury such as burn, trauma, or sepsis), the contribution of ALA to gluconeogenesis increases like those of other AAs, in particular GLN. In these situations, most AAs taken up by the liver come from the muscles.

During starvation, another metabolic pathway is activated: ketogenesis is mainly supported by free fatty acid metabolism, but one AA, LEU, also contributes. This may seem paradoxical because, as stated above, hepatocytes do not express BCAA-T. However, hepatocytes express all the other enzymes required for ketone body (KB) production, in particular the highly regulated enzyme branched-chain ketoacid-dehydrogenase (BCKA-dh) and so can metabolize branched-chain keto acids (BCKAs) coming from muscles. Thus, as described below, the production of KB from LEU is a typical example of the importance of inter-organ exchanges in AA metabolism.

Muscle Metabolism

Muscles contain 50% of the proteins in the human body and the largest pool of free AAs (i.e., 87 g in a male weighing 70 kg as compared to the plasma pool only 1.2 g). Therefore, muscles are often considered as a reserve of AAs, either directly (i.e., as free AAs) or indirectly (i.e., in the form of proteins). This is not exact because every protein has a function (note: whereas glycogen is only a reserve of glucose and has no other function). Therefore, in catabolic states or starvation, loss of proteins is accompanied with a loss of functions.

After a meal, arterio-venous measurements indicate that all AAs are taken up by the muscles to support protein synthesis.

At the post-absorptive state, all but one (i.e., GLU) are released by the muscles. It is noteworthy that ALA+GLN together represent 60% of the total AAs released by muscle, whereas they form less than 20% of protein content. This underlies the fact that most ALA and GLN come from *de novo* synthesis in the muscle. The carbon chain required for ALA synthesis comes from anaerobic degradation of glucose, and the amino moiety comes from transamination with GLU. The resulting α -KG is retransaminated by BCAA-T releasing BCKAs from BCAAs (Figure 1). Ultimately, 18% of the glucose taken up by muscle is metabolized into ALA and 12.5% of the nitrogen contained in circulating ALA comes from LEU. For GLN, the carbon chain comes from GLU, and GLU comes both from transamination and from the bloodstream. The ammonia required for the amidation of GLU comes from oxidative deamination of AAs and from the degradation of purine bases (Figure 1).

Table 2 Some amino acid functions

Function	Amino acid	Example
Constituent of proteins	20 AAs	
Hormone precursor	Phenylalanine	Tyroxine
	Tyrosine	Catecholamines
	Tryptophan	Serotonin
Mediators	Glutamate	Glutamate, GABA
	Glutamine	Glutamine
	Arginine	Nitric oxide
Binding of calcium	Glutamate	γ -Carboxyglutamate
Collagen structure	Proline	Hydroxyproline

GABA, γ -aminobutyric acid.

Inter-Organ Exchanges

Every tissue or organ possesses enzymatic equipment that is specific both qualitatively and quantitatively. Correspondingly, each tissue plays a specific role in nitrogen homeostasis. This explains the importance of inter-organ exchanges, each organ contributing as a provider of those AAs that others are unable (or not sufficiently able) to produce. The inter-organ exchanges highly depend on the feeding state (i.e., post-prandial vs. post-absorptive).

Figure 1 *De novo* synthesis of alanine and glutamine in muscles at the post-absorptive state. IMP, inosin monophosphate; BCAA, branched-chain amino acid; BCKA, branched-chain keto acid.

At the post-prandial state, as mentioned above, there is major AA splanchnic sequestration. AAs appearing in the general circulation are taken up by peripheral tissues, especially muscles.

At the post-absorptive state, the body must use its stores to generate the energy required. Lipolysis and glycogenolysis contribute to this process. However, the glycogen stores are limited and as fasting progresses, the glucose supply becomes more and more dependent on gluconeogenesis. This process implies the transfer to the liver of gluconeogenic AAs such as ALA and GLN. As described earlier in this article, the nitrogen moiety ultimately comes from BCAAs. This fact has two consequences:

1. Since BCAAs are EAAs (i.e., no possibility of synthesis in humans), their sole source is protein breakdown. Hence, gluconeogenesis in the liver results in net protein breakdown in muscle.
2. BCKAs resulting from BCAA transamination are poorly metabolized in muscles (except in severe catabolic situations where BCKA-dh is activated by pro-inflammatory cytokines) and therefore released in the bloodstream. They are then taken up by the liver, where two of them (α -ketoisocaproate and α -ketomethylvalerate) contribute to ketogenesis.

Gluconeogenic AAs taken up by the liver are readily transformed into glucose and this is favored by increased glucagon levels and decreased insulin secretion. Of course, synthesis of one molecule of glucose from one molecule of AA requires the removal of the N-residues. This is the job of ureagenesis. This process has an important consequence: each molecule of glucose produced in this pathway leads to the irreversible loss of (at least) one N-residue from net muscle proteolysis. This explains why in conditions of prolonged food restriction or when energy demand increases (e.g., in injury), a characteristic sign of metabolic adaptation is loss of muscle mass.

Glucose produced by the liver is taken up by glucose-dependent tissues. In the muscle, part of glucose is used anaerobically, leading to further generation of ALA, producing an ALA-glucose-ALA cycle also called the Cahill cycle.

At the whole-body level, this cycle makes no sense energetically because anaerobic glucose consumption generates little adenosine triphosphate (ATP) and gluconeogenesis consumes at least the same amount of ATP. However, reasoning at the tissue level casts a different light: in the post-absorptive state the liver is rich in energy owing to β -oxidation of free fatty acids from lipolysis in adipose tissue, whereas muscle is somewhat depleted in energy. Therefore, the Cahill cycle corresponds ultimately to the transfer of energy from an organ that is energy rich (the liver) to a tissue that demands energy (muscle) at the cost of net protein breakdown.

Final Products of AA Metabolism, Elimination of Surplus Nitrogen

N-metabolic products of AAs are mostly excreted in urine. Only an average 7 mg kg^{-1} body weight in males and 8 mg kg^{-1} in females is removed daily in other ways: shed skin (5 mg kg^{-1}), nasal secretions, shed hair, menstrual losses, etc.

Elimination of nitrogen cannot be carried out directly as ammonia because this substance is toxic for the central nervous system at plasma concentrations above $50 \mu\text{mol l}^{-1}$. Yet the equivalent of a mole of NH_3 has to be cleared everyday. For this reason, in humans, the main form of nitrogen elimination is urea, a water-soluble nontoxic compound synthesized by the liver.

However, not all the ammonia must be converted into urea, because ammonia plays a key role in acid-base homeostasis, in particular in the kidney.

Ureagenesis

The urea cycle is partly cytoplasmic and partly mitochondrial. Only the liver possesses all the enzymes required to synthesize urea from ammonia, and this pathway is strictly located in periportal hepatocytes.

Five enzymes are involved: carbamoylphosphate synthase (CPS), ornithine carbamoyltransferase (OCT), argininosuccinate synthase, argininosuccinate lyase, and arginase.

Ureagenesis is governed by three different types of regulations:

1. Regulation by the availability of precursors: the rate of flux of AAs toward the liver is a key regulator of ureagenesis; the more AAs the liver takes up, the higher is the rate of ureagenesis. AAs may come from food in the post-prandial phase or from muscles in the post-absorptive phase. Conversely, during prolonged starvation, urea production declines simply because the muscle efflux of AAs decreases. All the AAs are not equally ureogenic: GLN, ALA, and ARG make the most contribution.
 - GLN is hydrolyzed into GLU and ammonia by glutaminase present in large amounts in periportal hepatocytes. This reaction forms a ureagenesis amplification loop because the product of the reaction (ammonia) has the unusual property of activating glutaminase. The accumulation of GLU, the other product of the reaction, allows the synthesis of N-acetylglutamate, the regulatory role of which is described next.
 - ALA is transaminated into PYR and in parallel α -ketoglutarate gives rise to GLU. This GLU forms a

pool distinct from those described above: a second transamination reaction turns oxaloacetate into aspartate, which provides the second nitrogen donor in ureagenesis.

- ARG is very ureagenic because (1) it is the direct precursor of urea and (2) it plays a key role in the allosteric regulation of ureagenesis.
2. **Allosteric regulation: role of *N*-acetylglutamate.** This substance plays a key role in ureagenesis regulation because it is the allosteric regulator of CPS, the enzyme controlling the entry of ammonia into the cycle. *N*-acetylglutamate synthesis is catalyzed by *N*-acetylglutamate synthase, which is strongly activated by ARG. Hence, the flux of substrates (GLN, NH_3 , and ARG) and the allosteric regulation of CPS act synergistically to modulate ureagenesis both upstream and downstream.

When protein intake is low or null, the availability of precursors also plays a key role. In this situation, there is a derepression of arginase and OCT in the enterocytes and since, in adults (see below the specific situation of babies), the gut does not express ASS and ASL, this organ releases CIT instead of ARG in the portal vein. Of major importance CIT is not taken up by the liver. Hence, decrease in ARG availability for the liver slows down ureagenesis. Of note, CIT is largely extracted by the kidneys which exhibit ASS and ASL activities but not those of other urea cycle enzymes. Thus, the kidney releases ARG which is required by other tissues. Taken as a whole, this forms the ARG–CIT–ARG inter-organ cycle.

3. **Hormonal regulation.** This regulation operates at two levels:
 - On substrate availability: cortisol increases proteolysis and muscle efflux of AAs; glucagon promotes their transport into hepatocytes and further metabolism into ureagenesis and gluconeogenesis.
 - On the activity of enzymes, especially ASS and ASL.

Ammoniogenesis

This pathway is located in kidney tubular cells and is 80% supported by GLN. The first step is mediated by type I phosphodependent glutaminase, an enzyme activated by acidosis; GLU can then be transaminated into α -ketoglutarate or deaminated by GLU dehydrogenase. This last reaction is strongly activated by acidosis, further increasing the flux of NH_3 . NH_3 passes freely into the lumen, where it combines with protons to form the ammonium ion, which cannot return to cells.

The one-way flux of NH_3 means that during acidosis (i.e., high amount of H^+ in the lumen) the intra-cellular NH_3 level is low, derepressing GLU-dh. In turn, this favors GLU metabolism and low GLU derepresses glutaminase. Hence, it appears that ammoniogenesis is an adaptative pathway that plays a fundamental role in metabolic acidosis.

Relationship between Ureagenesis and Ammoniogenesis: A Contribution to Acid–Base Homeostasis

The observations described above underline the unique role of GLN as a donor of nitrogen for both ureagenesis and ammoniogenesis. However, heavy consumption of GLN in

ureagenesis is not compatible with an increased demand by the kidney in acidosis. A balance between these two almost exclusive processes is achieved, thanks to an anatomical detail – the liver contains two different hepatocyte populations:

- Perportal hepatocytes (93% of the total), which possess a glutaminase activity and enzymes of the urea cycle.
- Perivenous hepatocytes, which form only 7% of the total but have a metabolic activity 100 times higher. These cells possess GLN synthase activity. Hence, catabolism and synthesis of GLN are two processes that occur simultaneously in the liver, but at a different rate according to the situation.

Physiologically, most of the GLN from the portal vein is taken up by perportal hepatocytes, and the liver is a net consumer of GLN. In acidosis, hepatic glutaminase is inhibited (note: acidosis activates kidney glutaminase and inhibits the liver isoform). Consequently, GLN remains available for amino acid metabolism into the kidney.

Hormonal Control of Amino Acid Metabolism

Physiologically as well as in disease, hormones play a key role in the control of AA metabolism, with a balance between anabolic and catabolic hormones.

Anabolic Hormones

1. **Insulin.** Insulin exerts actions at every level of AA metabolism at the post-prandial state:
 - (a) It increases the cell transport of numerous AAs, especially in muscle and liver.
 - (b) It favors net protein anabolism by increasing protein synthesis and by decreasing protein breakdown. Insulin effect is re-enforced by LEU. Both are regulating positively the mammalian target of rapamycin (mTOR) signaling pathway. Upstream to mTOR, insulin action is dependent of AKT, whereas LEU is not.
 - (c) It decreases gluconeogenesis both by decreasing the availability of precursors and by inhibiting key enzymes of this pathway.
2. **Growth hormone (GH).** GH stimulates protein synthesis and decreases protein breakdown both at the whole body level and in muscles. However, at the basal state, the effects of GH on protein metabolism are likely of minor biological importance. Conversely, during fasting (where GH is the only anabolic hormone to increase), the anabolic effects of GH are consistent, certainly as a counter-regulatory agent in order to avoid excessive protein loss.

Catabolic Hormones

1. **Glucagon.** Like insulin, glucagon activates the A system of AA transport, but unlike insulin, glucagon favors the use of AAs in gluconeogenesis. In addition, glucagon favors proteolysis (through macro-autophagy) in the liver.
2. **Cortisol.** Cortisol induces hyper-amino-acidemia because although it increases hepatic, intestinal and renal uptake of AAs, it increases their muscle release even more strongly.

Figure 2 Cortisol and glucagon act synergistically to drive AAs from muscle to the liver.

In addition, cortisol favors net protein breakdown. Hence in a stress situation, cortisol and glucagon have a synergistic action (**Figure 2**) leading to a unidirectional flux of nitrogen from the muscle to the liver.

3. **Cytokines.** Physiologically, their role is minor except with the advance in age (see below). However, in disease, pro-inflammatory cytokines (e.g., tumor necrosis factor α , interleukins 1 and 6) are overproduced and act synergistically with glucagon and cortisol on AA metabolism.

Some Specificities of Amino Acid Metabolism along the Life Cycle

Infants. After birth, the enterocytes express ASS and ASL and therefore the gut releases ARG and not CIT. The reason is that the milk does not contain a sufficient amount of ARG to cover requirements.

Elderly. With aging there is an increased sequestration of amino acids into the splanchnic area after a protein meal and therefore a decrease in availability of amino acids at the periphery to stimulate muscle protein synthesis. In addition, the anabolic signal of insulin and LEU is blunted at the muscle level. One possible explanation is the low-grade inflammation which develops with aging: the increase in pro-inflammatory cytokine secretion may be involved in metabolic alterations described just above. This explains the occurrence of sarcopenia (a decrease in muscle mass and functions) in the elderly.

Glossary

Anti-angiogenesis The process by which blood vessel formation is inhibited. Disruption of this activity is an effective way to prevent tissue proliferation, as is encountered in tumor growth.

Carboxypeptidase One of two major classes of exopeptidases. They cleave protein and peptide substrates sequentially from the carboxyl terminal end.

Endopeptidase One of two major classes of proteolytic enzymes (the other being exopeptidases) that cleave peptide and protein substrates at internal peptide bonds.

N-End rule pathway An intracellular pathway in which selected N-termini of proteins are recognized by a specific part of the ubiquitin tagging machinery of the cell, leading to their degradation via proteosomal cleavage.

Open reading frames (ORFs) Genome sequences that can be continuously interpreted in an unbroken protein sequence. They generally, but not always, correspond to true structural genes.

Proteosome An intracellular suborganelle (or protein machine) composed of multiple subunits organized in a stack of four seven-membered rings. The subunits of the inner rings are proteolytic enzymes that degrade target proteins into short peptides, which are then either further broken down into free amino acids by exopeptidases action or (in the immune system) presented as cell-surface antigens to elicit an antibody response. When associated with additional subunits that recognize appropriately marked proteins, it is the principal entity responsible for intracellular protein turnover.

Zinc-finger domains Short amino acid sequences that contain four appropriately spaced residues capable of binding a zinc ion through their side chains. This structure, usually predictable from sequence alignments, is often involved in binding to both protein and nucleic acid partners.

General Description

Properties

Aminopeptidases occur in both soluble and membrane-bound forms and can be found in various cellular compartments as well as in the extracellular environment. The majority are metalloenzymes; that is, they minimally require a metal cofactor at the catalytic site for activity, which is usually zinc ion but can be a number of other metal ions, including Fe^{2+} , Mn^{2+} , and Co^{2+} . There are subclasses containing one and two metal ions. In some cases, the physiologically relevant metal is uncertain. There are a few aminopeptidases, particularly of the dipeptidyl- and tripeptidyl-peptidase type, that are classified as serine or cysteine proteases. Aminopeptidases can be processive, meaning that they will continue to degrade the substrate until they reach an unfavorable residue (or combination of residues), and nonprocessive. The latter are usually highly specific for an amino acid type and do not further degrade the substrate after the initial susceptible residue is removed.

Functions

The physiologic functions of aminopeptidases can be divided into three main categories: processing/maturation, activation, and degradation. The enzymes involved in the first two areas usually are highly specific, are nonprocessive, and tailor the N-terminus of proteins or peptides either co- or posttranslationally to induce activity or to allow for subsequent modifications that will, in turn, affect activity. Degradation (including

inactivation) can also use specific enzymes, particularly where individual bioactive peptides are targeted, but most often involves nonspecific enzymes that participate in protein turnover by the reduction of small peptides, arising from proteosomal cleavage of targeted proteins, to amino acids or by the extracellular degradation of peptides arising from a number of sources.

N-Terminal Cotranslational Processing

One of the best-understood functions of aminopeptidases is their role in N-terminal cotranslational processing. Protein synthesis that is directed by the genetic material is universally initiated by the amino acid methionine (in prokaryotes, N-formyl methionine), but the majority of the protein mass in organisms does not reflect this event; that is, most proteins (at least those commonly studied to date) do not have an N-terminal methionine residue. Extracellular proteins that are exported through the endoplasmic reticulum and proteins imported into mitochondria (as well as related organelles such as chloroplasts) lose their respective signal peptides (usually 20–25 amino acids), including the initiator methionine, through the action of specific signal peptidases, which are endopeptidases. The removal of the initiator methionine from intracellular proteins is accomplished through the action of a specific class of aminopeptidases (clan MG of the metallo-peptidases) designated methionine aminopeptidases (MetAPs). All living organisms apparently have at least one form of this

enzyme, and they require this activity for vitality. There are several reasons for this: (1) methionine is a relatively scarce amino acid, and failure to return a large percentage of the methionine used in the initiation process for reuse (in a variety of activities) leads to a starvation condition that is ultimately lethal; (2) many proteins are subsequently modified on the α -amino group of the newly exposed residue (but can also occur on methionine residues that are not removed) that in many cases is a requirement for their further function; and (3) a few proteins use the newly exposed penultimate residue as a part of their active structure. The reason that methionine is not removed from all N termini is apparently due to its role as a protecting group against degradation by the N-end rule pathway.

MetAP Specificity

The substrate profile of the MetAPs, despite other distinguishing physical characteristics, is highly conserved over all living organisms, suggesting that it is a very ancient enzyme. Briefly, susceptible substrates have the seven smallest amino acids (glycine, alanine, serine, threonine, cysteine, proline, and valine) in the adjacent (penultimate) position to the methionine. In yeast, a little over one-half of the open reading frames (ORFs) are predicted to code for proteins with these N-terminal sequences, but in terms of mass the percentage of soluble proteins is much higher, perhaps as high as 80%. Because essentially all exported and transmembrane proteins (which may account for as much as one-third of the total protein in a cell) and most of the proteins imported into the mitochondrion also lose their N-termini through cleavage of their signal peptides, which are in turn degraded to amino acids, there is a very high degree of recyclization of initiator methionine.

Properties of MetAPs

Structural organization

The basic catalytic domain, first defined by X-ray analyses of the *Escherichia coli* enzyme, is 30 kDa in mass and contains two metal ions at the active site. It has an internal symmetry (described as a pita bread fold) suggestive of an early gene duplication event. This structure appears, with only minor variations, to be found in all eubacteria and represents the type 1 isoform. Archaeobacteria contain a different but related (homologous) form of MetAP, principally characterized by an insertion of approximately 65 residues that forms an extra highly helical domain on the surface of the protein. It is designated type 2. Eukaryotes contain both types and, in addition, each contains an amino terminal extension. The N-terminal segment of the type 1 enzyme contains zinc-finger domains that are thought to act as a tether to tie this enzyme to the ribosome. The corresponding segment of the eukaryotic type 2 proteins is marked by extended stretches of polyacidic and basic amino acids. The function of this domain is unknown. The overall organization of the MetAP family is shown in Figure 1.

Metal use

These enzymes were initially characterized as using two Co^{2+} , based on early experiments with the eubacterial MetAPs. Subsequently, it was shown that multiple metals could be used in

Figure 1 Schematic presentation of the structural organization of the MetAP family. Separate domains are indicated by color (magenta, N-terminal extension characteristic of MetAP2s; brown, N-terminal extension with putative Zn-binding domains characteristic of MetAP1s; light blue, catalytic domain insert characteristic of MetAP2s) and are presented approximately to scale. Major deletions (and insertions) deduced from sequence and structural comparisons are indicated as gaps. M denotes the site of a metal ligand; F indicates the location of the histidine modified in type 2 enzymes. The number of residues for each protein is given in the column at the right. Reproduced from Bradshaw RA and Yi E (2002) Methionine aminopeptidase and angiogenesis. *Essays in Biochemistry* 38: 65–78.

many of the forms, particularly the *E. coli* enzyme, which is active with Fe^{2+} , Zn^{2+} , Ni^{2+} , and Mn^{2+} , in addition to Co^{2+} . It is possible that, depending on availability, the eubacterial enzymes may use different metals. In recent studies in eukaryotes, Mn^{2+} has emerged as the preferred candidate for the type 2 enzyme, whereas Zn^{2+} remains the most likely metal cofactor for the type 1 enzymes under physiological conditions. Although early studies suggested that the MetAPs used a bivalent metal structure, they can clearly function with only a single metal ion present. In all cases, the metal ions are bound through five amino acid side chains and these are well preserved in all the isoforms in both prokaryotes and eukaryotes.

Roles of the MetAP Isoforms

The substrate specificity of all of the isoforms is generally the same as just described and is heavily predicated on the nature of the penultimate residue. Substrate length, in *in vitro* studies, does have some effect but it is unclear whether this is of significance *in vivo*. Similarly, different metal ions could also affect substrate selection, but this has not been systematically demonstrated. Null mutations (manipulations that prevent the expression of a gene) in yeast demonstrate some measure of redundancy because cells will survive with one or the other of the isoforms but not when both are eliminated. Deletion of the single gene in prokaryotes is also lethal. Nonetheless, there is both direct and indirect evidence to support the view that the two isoforms have different cellular functions. MetAP1 is thought to function as the main processing enzyme and be physically associated with the ribosome in a position to hydrolyze the methionine from germane nascent chains during protein synthesis. MetAP2 is thought to be a soluble enzyme and to probably provide secondary processing for substrates that

improperly escape the action of MetAP1. However, it is clearly involved in other activities as well. This is illustrated by a class of irreversible chemical inhibitors that are highly selective for MetAP2, which cause cell-cycle arrest in endothelial cells (but not cell death) resulting in anti-angiogenesis. These potential drugs are being refined for use in treating tumors. Presumably, this inhibition results from the failure of MetAP2 to process a select protein or subset of proteins involved in mitosis of these cells, but their nature is unknown. Downstream sequences probably are responsible for rendering these select targets susceptible to MetAP2 but not MetAP1. MetAP2 also functions to inhibit the phosphorylation of eIF2 α and thereby promote translation. This activity is entirely distinct from its catalytic one and is not connected to its cell-cycle functions because the inhibited protein is still fully functional as a phosphorylation inhibitor. It is thus one of many proteins known to have dual (and often unrelated) functions.

Glossary

Folding motif The three-dimensional (3-D) shape pattern exhibited by a folded protein, consisting of the secondary structural units (e.g., α -helix and β -strands) accessed by different elements of the primary sequence, and how those secondary structural units interact with one another in space. Although there are tens of thousands of protein sequences coded within the human genome, it is believed that the 3-D structures of these proteins will ultimately be described by perhaps only a few hundred folding motifs.

Glial cells Non-neuronal, accessory cells in the brain that are responsible for maintaining brain structure and development and for fighting infection.

Membrane depolarization Loss of chemical potential across a membrane.

Molecular chaperones Enzymatic protein assemblies that are responsible for detecting, reversing, and, where necessary, eliminating failed products of protein folding, such as misfolded and aggregated proteins.

Nuclear magnetic resonance A type of spectroscopy in which the unique covalent and noncovalent environments

of atoms in molecules in solution can be assessed, allowing for construction of a high-resolution structural model of the 3-D relationships between atoms.

Ubiquitin–proteasome system A complex pathway of enzymes responsible for marking and destroying proteins that are no longer required by the cell due to their being obsolete or defective. Such proteins are first marked by the attachment of the small protein ubiquitin, at which point they are recognized and destroyed by the proteasome, a large protein machine consisting of proteases and other enzyme activities.

X-ray crystallography A technique for determining at high resolution the spatial relationships between atoms in a molecule in the solid state, by the detailed diffraction pattern generated when a molecular crystal is exposed to X-ray beams.

X-ray fiber diffraction An intermediate-resolution version of X-ray diffraction analysis, not requiring a crystalline form, in which repeated patterns of a structure can be recognized from a limited diffraction pattern.

Amyloid is an aggregated protein structure consisting of unbranched microscopic fibrils often found in dense tissue deposits and associated with a variety of human diseases, including a number of significant neurodegenerative disorders. In its broadest usage, the term amyloid does not pertain to a specific protein molecule or sequence, but rather to a general folding pattern, or folding motif, that appears to be accessible to many, if not all, polypeptide chains. Although the three-dimensional structures of these proteins in their native states can vary enormously, the abnormal amyloid structures that they form exhibit a characteristic folding pattern, called a cross- β structure, that differs from that of the native state structure.

Introduction

Amyloid formation thus involves a protein misfolding reaction. Amyloid fibrils are generally very stable and quite insoluble in native, aqueous buffer. In a way, amyloid is a foreign substance composed of self-proteins, but it is not easily recognized and removed as a foreign substance by the immune system, for reasons that are not well understood. In some disease states involving amyloid deposition, the amyloid deposit is directly involved in the disease mechanism, whereas in other cases its mechanistic role is less clear. In some microorganisms, specific proteins and protein domains appear to

have evolved for the purpose of making amyloid fibrils that play an important, positive role in the cell. In most cases, however, amyloid is a pathogenic structure, formed by accident under conditions of molecular, cellular, or organismic stress, from proteins that evolved to fold and function in quite different structural states. The recognition that proteins not known to be involved in amyloid disease can be induced to form amyloid fibrils, through exposure to certain nonnative conditions *in vitro*, has led to a picture of the amyloid motif as a general default structure in protein folding accessible to many, if not all, polypeptide sequences. Notwithstanding the predominant usage described above, the word 'amyloid' is also occasionally found as part of the names of specific proteins. These proteins tend to be associated in some way with the amyloid phenomenon, either as proteins capable of making amyloid fibrils (such as serum amyloid A, islet amyloid polypeptide (IAPP), and β -amyloid (also known as A β)) or as proteins that interact with amyloid fibrils (such as serum amyloid P component).

History

Waxy masses found at autopsy in the liver and spleen have been observed in humans since the seventeenth century. In 1854, Virchow reported that an iodine stain thought to be

specific for starch generated a positive test on such material and therefore classified these structures as amyloid (starch-like). Although 5 years later Friedreich and Kekule demonstrated that these deposits contained negligible carbohydrate, the name amyloid has been retained. In 1922, Bennhold introduced the use of the dye Congo red to stain tissue amyloid deposits. After the dye binds, it exhibits an apple-green birefringence when examined by polarized microscopy that sharply distinguishes amyloid from other tissue components (Figure 1). Ever since, Congo red has been the primary method by which pathologists identify amyloid deposits in tissue samples. In 1927, Divry showed that the cores of senile plaques, the cortical structures that Alzheimer linked with early-onset senile dementia in his classic 1906 paper, exhibit the Congo red birefringence characteristic of amyloid. Amyloid plaques are recognized as one of the pathological hallmarks of Alzheimer's disease (AD) and it is believed that some aggregated form of the main protein component of the amyloid fibrils in these plaques plays a direct role in AD etiology. Although it had long been recognized that the main chemical component of amyloid fibrils is protein, it was not until the pioneering work of the Glenner and Benditt groups in the early 1970s that it was realized that amyloid fibrils are predominantly composed of specific protein sequences rather than a broad mixture of protein molecules. Glenner showed that amyloid extracted from primary amyloidosis patients contained the immunoglobulin light chain molecule, and Benditt found that amyloid from tissues of chronic inflammation patients consisted of a new protein called amyloid A. Other clinically distinct forms of amyloid were soon thereafter shown to have different characteristic protein constituents. In the mid-1980s, Glenner isolated and characterized by amino acid sequencing the previously unknown peptide $A\beta$ as the principal component of AD amyloid fibrils. By the end of the twentieth century, many naturally occurring amyloid proteins had been characterized and the list continues to grow with the development of more sensitive means of analysis.

Figure 1 Rings of amyloid detected by Congo red staining and polarized microscopy in the spleen of a mouse with serum amyloid A amyloidosis. Courtesy of professor Jonathan Wall, University of Tennessee.

Amyloid Diseases

Range of Amyloid-Related Diseases

Table 1 lists some of the over 30 human disease states in which amyloid fibrils have been observed, as characterized by the principal organ involved and the principal protein component of each. Amyloid diseases can occur both in the brain and in the rest of the body. The systemic amyloid diseases tend, as a general rule, to involve large deposits of amyloid that in extreme cases dramatically increase the size of the affected organ. In these cases, the toxicity of the amyloid deposit may be largely due to the mass of deposited material and its ability to disrupt normal tissue structure and function. In some peripheral amyloid diseases, the amyloid deposits are localized to a particular tissue. Such is the case in pancreatic amyloid, which is found in over 90% of adult-onset (type 2) diabetes patients (despite this high incidence, the pathogenic role of amyloid deposition in diabetes is not yet known). By contrast, in other amyloidoses, protein deposits can be found in a variety of tissues. Amyloid is also observed in a number of brain diseases. In AD, extracellular amyloid deposits are found in the cerebral cortex, usually embedded with fragments of neuronal processes and surrounded by activated glial cells. In Huntington's disease, amyloid deposits are found in both the cytoplasm and the nucleoplasm of particular neurons in the cortex and elsewhere. In Parkinson's disease, large neuronal deposits called Lewy bodies are rich in the protein α -synuclein. In each of these brain diseases, the mechanistic role of protein deposits has not yet been established.

Table 1 Major polypeptide components of pathogenic amyloid deposits in humans

<i>Polypeptide</i>	<i>Major disease states</i>
Transthyretin	Heart, kidney, and peripheral neuropathy
Serum amyloid A	Kidney and peripheral neuropathy
Immunoglobulin light chain	Kidney and heart
Immunoglobulin heavy chain	Spleen
β_2 -Microglobulin	Carpal tunnel syndrome and osteoarthritis
Lysozyme	Non-naturopathic visceral amyloid
Islet amyloid polypeptide	Diabetic pancreatic islet cells
Fibrinogen α -chain	Kidney
Apolipoprotein A1	Peripheral neuropathy and liver
Atrial natriuretic peptide	Heart
Amyloid β -protein ($A\beta$)	Brain (Alzheimer's disease and cerebral amyloid angiopathy)
α -Synuclein	Brain (Parkinson's disease)
Huntingtin polyglutamine sequence	Brain (Huntington's disease)
Prion protein (PrP)	Brain (Creutzfeldt-Jakob disease and mad cow disease)
Cystatin C	Brain (cerebral amyloid angiopathy)
Gelsolin	Brain (cerebral amyloid angiopathy)
ABri	Brain (familial British dementia)

Physiological Factors in Amyloid Formation

Although much remains to be learned about the events that trigger amyloid deposition, it is clear that a variety of factors are involved. Some well-established factors are molecular aspects of the proteins themselves. Since the rates of aggregation reactions, such as amyloid formation, depend on concentration, dramatic increases in the amount of the amyloidogenic precursor protein can initiate amyloid formation. This is the case for the protein serum amyloid A, which increases in concentration in response to infection and, when persistently elevated, can deposit as amyloid. Similarly, the reason patients with Down's syndrome invariably develop AD may be because the extra chromosome associated with the disease contains the gene for the amyloid β -protein precursor (APP), the protein from which the main plaque component A β is generated. The presence of a third active copy of the APP gene in cells results in increased levels of A β , which in turn serves to initiate, or nucleate, fibril formation. One of the unsolved mysteries of amyloid disease is how nucleation of amyloid growth occurs in most disease states. When studied *in vitro*, proteins responsible for amyloid disease often require extremely high, nonphysiological concentrations for nucleation and growth of amyloid fibrils. This indicates that there are unknown specific structures and/or environments in the body that facilitate nucleation. Amyloid plaques typically contain other proteins in addition to the main fibril component and one role of some of these proteins may be to contribute to amyloid formation by helping to stabilize the fibrils and protect them from normal degradative mechanisms. Amyloid diseases are often age related, leading to the speculation that sporadic amyloid deposition may be a not uncommon occurrence that is held in check in the young and healthy but which advances when normal surveillance mechanisms break down in the aged. This may account for the finding that, in the inherited amyloidosis associated with mutant forms of amyloidogenic precursor proteins, the diseases generally occur later in life, despite the fact that the proteins are expressed from birth.

Prions and Amyloid Enhancement Factor

In one group of amyloid-related brain diseases, a group including Creutzfeldt-Jakob disease, mad cow disease, and the sheep disease scrapie, the conditions can be transmitted by ingestion of prion particles, misfolded versions of a normal cellular protein, from the nervous system tissue of a previous victim. Although it is not firmly established that the actual prion particle or state itself is an amyloid fibril, the ability of prion infectivity levels to be amplified in the body bears an intriguing resemblance to the ability of amyloid fibrils to amplify themselves from a pool of precursor protein, through seeding. All mammals express a version of the prion precursor protein (PrP), which has a normal function and does not normally lead to disease. Except in rare instances of sporadic and genetic forms of the disease, prion-associated diseases are observed only when the animal has been exposed to exogenously supplied prion particles, which appear to act *in vivo* as seeds or templates for the propagation of new prions from the normal PrP pool. This scenario is reminiscent of the phenomenon that serum amyloid A amyloidosis can be accelerated in

experimental animals by administration of an agent called amyloid enhancement factor (AEF). AEF extracted from the amyloidotic spleen of a mouse and injected intravenously into new mice can induce the rapid development of amyloid deposits compared to untreated controls. Biochemical studies are consistent with AEF being essentially composed of amyloid fibrils, although the presence of an important minor component is difficult to rule out. A possible strong connection between the AEF and prion phenomena has been suggested by experiments showing that AEF, as well as pure amyloid fibrils created *in vitro*, can induce amyloid disease in mice when placed in their drinking water. Thus, although most amyloid diseases are not considered to be transmissible, the results in this experimental system suggest that various amyloid fibrils might be capable of behaving as prions in some circumstances.

Toxicity of Amyloid Fibrils

Although in some peripheral conditions, amyloid can cause life-threatening disease by accumulating in such high mass that normal tissue structure and function are disrupted, in other cases, particularly in the neurodegenerative diseases, the accumulated mass of amyloid is very low compared to the surrounding cell mass. In these cases, the mechanism(s) by which amyloid fibrils cause cell death or cell dystrophy is not at all clear. Whether there is a uniform toxic mechanism in all diseases or different mechanisms for different diseases is also unknown. Toxicity mechanisms under investigation include the following: (1) collateral damage caused by immune responses to an amyloid deposit; (2) membrane depolarization resulting from channels created by amyloid fibril assembly intermediates inserted into membranes; (3) recruitment of other proteins into growing aggregates, which has the effect of denying the cell the activity of the recruited protein(s); and (4) disruption or overwhelming of the normal cellular apparatus for breakdown and elimination of misfolded proteins, such as the ubiquitin-proteasome system and the molecular chaperones.

Evolved Amyloid

As far as is known, most protein sequences in evolution were selected for their abilities to efficiently access functional, folded states, while being either unselected, or selected against, with respect to the ability to make amyloid fibrils. Thus, in most cases where amyloid forms, the amyloid can be viewed as an accidental, environmentally induced structure never intended by nature. There are several examples, however, of proteins whose ability to make amyloid fibrils in microbial cells is beneficial to the organism. Yeast prions, for example, function through their ability to form and seed amyloid fibrils and in doing so they modulate the levels of the soluble form of the prion protein in the cell, the fluctuations in which play metabolic and ultimately regulatory roles. In another example, a complex system of proteins in *Escherichia coli* is responsible for producing an extracellular amyloid fibril that plays a role in cell adhesion. The existence of functional, beneficial amyloid might be viewed as an example of nature's ability to exploit to advantage the novel properties of the products of evolution.

Amyloid Proteins

Range of Amyloid Proteins

Amyloid fibrils composed of different proteins share a number of common structural features, despite the fact that these proteins, in their native states, vary widely in structure, cellular locations, and properties. For example, the amyloid protein transthyretin is a tetramer of subunits with a total molecular weight of 55 kDa. In contrast, small peptides of approximately 40 amino acid residues, such as A β and IAPP, and fragments of IAPP as short as pentapeptides, are also capable of amyloid fibril formation. Proteins can grow into amyloid fibrils regardless of the nature of their normal folding patterns. In their native states, α -synuclein exhibits no stable structure in solution, transthyretin is dominated by β -sheet, lysozyme is a mixed α -helix/ β -sheet protein, and serum amyloid A is essentially fully α -helical, yet all are capable of forming amyloid fibrils. Most of the peripheral amyloidoses involve secreted proteins, whereas the nine different proteins responsible for nine expanded polyglutamine diseases – including Huntington's disease – are cellular proteins (which, in turn, are found in a variety of subcellular locations). Most amyloid proteins contain significant percentages of hydrophobic residues, but polyglutamine consists entirely of the relatively polar amino acid glutamine. One of the few patterns shared among amyloidogenic protein regions is the infrequent occurrence of proline residues, which strongly disfavor β -sheet – the dominant secondary structural feature of the amyloid fibril.

Molecular Factors in Amyloid Formation

Until the early 1990s, the unusually insoluble, fibrous, quasi-crystalline amyloid fibril was generally viewed as a structural form in which the subunit building block was essentially the native state of the amyloidogenic precursor protein, in a model analogous to structural models for aggregated sickle cell hemoglobin. A significant advance in the understanding of amyloidosis was the demonstration in the mid-1990s that amyloid formation is strongly enhanced when the folded state of a protein is destabilized by mutation or by the solution environment, indicating that fibril structure involves non-native states. These studies were later extended to show that denaturing conditions can induce amyloid formation even in some proteins not known to be pathogenic. It is clear that misfolding, that is, the rearrangement of the complex folded shape of a protein molecule, is central to amyloid formation. Thus, protein stability – the resistance of the folded conformation to misfolding/unfolding – is an important factor in determining susceptibility to amyloid formation. Extreme environments in the body, such as acidic cell compartments, may, in some cases, facilitate protein unfolding and therefore promote amyloid formation. Proteolytic removal of a portion of a protein by an endogenous protease can also be a destabilizing factor leading to amyloid formation. Notably, mutations that alter the primary structure of proteins can affect protein stability. In fact, many of the amyloid diseases involve amino acid substitutions in an amyloid precursor protein. The most common example is familial amyloidosis, caused by a variety of single point mutations in the protein transthyretin. In addition,

noninheritable, specific amino acid changes in immunoglobulin light chains are linked to a high risk of amyloidosis. Amino acid changes can contribute to the efficiency of amyloid formation not only by modifying the stability of the native state of the precursor protein, but also by modifying the stability of the amyloid fibril itself; an example of the latter is the ability of proline residues to destabilize amyloid structure.

Amyloid Assembly

The manner in which amyloid fibrils grow can be considered in terms of the kinetics of the process or the structures of assembly intermediates. Kinetically, amyloid fibril formation *in vitro* typically exhibits a lag time of hours to days, followed by a rapid growth phase. In many such cases, the lag phase can be abbreviated or eliminated if a small amount of fibril is provided as seed at the start of the reaction. Such behavior has been interpreted as evidence that fibril growth takes place by nucleated growth polymerization, a mechanism of colloidal assembly in which the initiation of aggregate growth depends on the sporadic generation of a highly unstable, highly organized nucleus state. However, it is far from clear how amyloid growth is initiated *in vivo* and it is possible, even likely, that other molecules or structures are involved, which would make the *in vivo* mechanism more akin to what in physics is referred to as heterogeneous nucleation. *In vitro*, after the nucleation (or seeding) phase has occurred, growth continues predominantly via the elongation of existing fibrils and it has been argued that this is a more realistic view of how amyloid develops *in vivo*. A number of assembly intermediates have been detected when amyloid growth is studied *in vitro*. Whether or not any of these can be considered to be true kinetic nuclei, some of these structures may have relevance *in vivo*. Amyloid growth from monomeric proteins seems to proceed via the formation of successively larger, more complex structures, from small globular aggregates to short curvilinear filaments to isolated straight and unbranched fibrils to bundles of fibrils. The early assembly intermediates in this progression appear to be more cytotoxic than the mature fibrils, leading to the speculation that assembly intermediates are the real culprits in disease pathogenesis. Little is known, however, about whether and how these intermediates might be formed in the body and how they might kill cells.

Amyloid Structure

Amyloid ultrastructure as revealed by electron microscopy (Figure 2) or atomic force microscopy shows fibrils to be relatively straight and unbranched, with diameters in the range of 80–160 Å. Fibrils have a characteristic twist, being composed of two to six protofilaments of diameter 30–40 Å. X-ray fiber diffraction studies reveal that fibrils and their constituent protofilaments are rich in a type of β -sheet structure known as cross- β . In this conformational structure type, the extended chain elements of the β -sheet are perpendicular to the fibril axis and the hydrogen bonds between the strands are parallel to the fibril axis. Beyond this level of resolution, little is known about the detailed protein folding of the amyloid motif because of imposing technical barriers to their study by the

Figure 2 An electron micrograph of an amyloid fibril grown in the laboratory from the Alzheimer's disease peptide A β . Courtesy of professors Indu Kheterpal and John Dunlap, University of Tennessee.

standard methods of X-ray crystallography and solution-phase nuclear magnetic resonance spectroscopy. Nevertheless, a number of structural models have been proposed and important insights continue to be obtained through lower resolution studies. The structure of the amyloid folding motif is important for a number of reasons, only one of which is their association with a variety of human diseases. It is clear that misfolded, aggregated proteins are formed routinely in the cell due to fundamental inefficiencies in the protein-folding process; understanding amyloid structure may help elucidate how the

cell manages to recognize and eliminate the products of folding mishaps. Mapping amyloid structure and assembly will also contribute to the understanding of this previously ignored aspect of the protein-folding reaction – unproductive side products. Finally, better structural information may allow a rational design approach to the development of anti-amyloid therapeutics.

Glossary

Anaplerosis The entry of substrates into the citric acid cycle as intermediates other than acetyl-CoA, thereby increasing the citric acid cycle pool size.

Carboxylation The introduction of a carboxyl group into a compound.

β -Oxidation The oxidative metabolism of fatty acids through a cycle of reactions that removes successive two-carbon units (acetyl-CoA) from the fatty acid.

The word anaplerosis (from the Greek, meaning to fill up) was coined in the 1960s by Sir Hans Kornberg to describe pathways that replenish intermediates in metabolic cycles. A metabolic cycle transforms a substrate with little or no change in the concentration of the cycle's constituents, the central process in energy substrate metabolism. A classic example for a metabolic cycle is the citric acid cycle. Here anaplerotic pathways mediate the entry of metabolites into the cycle as compounds other than acetyl-CoA and thereby replenish the pool size of the citric acid cycle. Other anaplerotic pathways are present in eukaryotic and prokaryotic organisms; however, this article focuses on anaplerosis as it relates to the citric acid cycle in mammalian tissues and the importance of anaplerosis in the maintenance of organ function.

Cycles have evolved because in a competitive environment the chances for survival are greatest if resources are used in an optimal way. For example, energy transfer in heart muscle is linked to a series of cycles, beginning with the circulation and ending with actin-myosin cross-bridge formation (Figure 1). Steady-state concentrations of metabolic intermediates in a cycle depend on their rates of synthesis and degradation. In other words, substrates entering the citric acid cycle as citrate (via the condensation of acetyl-CoA with oxaloacetate) do not cause a net change in the citric acid cycle pool size because the two carbons of acetyl-CoA are ultimately lost as CO₂ in the isocitrate and the α -ketoglutarate dehydrogenase reactions, respectively. In contrast, anaplerosis supplies compounds to the citric acid cycle through reactions other than those catalyzed by citrate synthase. These compounds replenish carbon intermediates lost primarily as amino acids (glutamate or aspartate) or as oxaloacetate.

The role of anaplerosis in the citric acid cycle is threefold. First, as intermediates are drained away during biosynthetic processes such as gluconeogenesis, glyceroconeogenesis, and amino acid synthesis, anaplerotic pathways replace them, assuring sufficient carbon flux for citrate synthesis and, hence, allow citric acid cycle flux to proceed unimpaired. These aspects of anaplerosis are especially important in the liver and renal cortex. Second, anaplerosis facilitates energy transfer in organs with high rates of energy turnover, such as the heart and skeletal muscle, especially under situations such as ischemia in which normal functioning of the citric acid cycle is impaired. Third, anaplerosis also regulates whole-body

metabolic homeostasis through the regulation of insulin secretion from the β -islet cells of the pancreas. We now focus on the mitochondrial anaplerotic pathways.

Anaplerotic Pathways

Substrates for Anaplerosis

The known anaplerotic pathways for the citric acid cycle are depicted in the schematic drawing of Figure 2. As a key component of all living cells, the citric acid cycle is highly organized and responds instantly to changes in its environment. The citric acid cycle is tied into a distributive system of energy transformation reactions (Figure 1) and flux through the anaplerotic pathways. The primary substrates for anaplerosis are lactate and alanine as precursors of pyruvate, although glutamate can be a physiologically significant anaplerotic substrate as well. In addition, the branched chain amino acids valine and isoleucine, as well as odd-chain fatty acids and their metabolic end product, propionate, serve as anaplerotic substrates.

Entry at Malate and Oxaloacetate

In the heart the major anaplerotic substrate in the heart is pyruvate. Although the majority of pyruvate entering the mitochondria is oxidatively decarboxylated (and most likely by CO₂ arising from pyruvate decarboxylation) and enters the citric acid cycle as acetyl-CoA, a portion is also carboxylated and enters the four-carbon (C-4) pool of the citric acid cycle. This conversion is catalyzed by either pyruvate carboxylase (PC, E.C. 6.4.1.1), forming oxaloacetate or by nicotinamide adenine dinucleotide phosphate (NADP)-dependent malic enzyme (E.C. 1.1.1.40), forming malate. While the NADP-dependent malic enzyme reaction is reversible, the reaction in the direction of malate production is slow and unlikely to play a significant role in anaplerosis. Another provider of C-4 intermediates in the citric acid cycle is aspartate, which undergoes transamination with α -ketoglutarate via aspartic aminotransferase to form oxaloacetate and glutamate. In contrast to the carboxylation of pyruvate, the entry of aspartate as oxaloacetate is balanced by the loss of α -ketoglutarate from the citric acid cycle, resulting in the homeostasis of citric acid cycle intermediates.

Entry via α -Ketoglutarate

Mitochondrial α -ketoglutarate can be readily formed from glutamate via transamination with pyruvate (forming alanine) or oxaloacetate (forming aspartate). The transamination of glutamate with oxaloacetate by glutamate oxaloacetate transaminase (E.C. 6.2.1.1) results in a gain of a C-5 intermediate at the same time that a C-4 intermediate is lost from the citric acid cycle. Of importance is that the mitochondrial pools of α -ketoglutarate and glutamate are in equilibrium and therefore labeling patterns of glutamate are identical to those for α -ketoglutarate. As discussed below, this relationship between α -ketoglutarate and glutamate can be exploited in measuring citric acid cycle flux, relative rates of contribution of substrates to the citric acid cycle, and rates of anaplerosis. Furthermore, glutamate can be converted to α -ketoglutarate and NH_4^+ by glutamate dehydrogenase, which

is present in a variety of tissues, including the liver, kidney, brain, heart, and skeletal muscle.

Entry via Succinyl-CoA

The citric acid cycle intermediate succinyl-CoA plays an important role in fatty acid and amino acid metabolism because it is the entry point of odd-chain fatty acids, propionate, and the branched chain amino acids valine and isoleucine into the citric acid cycle. Substrate entry as α -ketoglutarate or succinyl-CoA, in contrast to other anaplerotic pathways, is associated with the generation of energy-rich phosphates via a substrate-level phosphorylation. The reaction catalyzed by succinyl-CoA synthetase (E.C. 6.2.1.4) normally favors the conversion of succinyl-CoA to succinate and leads to substrate level phosphorylation of GDP to GTP. This energy-providing pathway becomes important under anaerobic conditions when ATP generation by oxidative phosphorylation is inhibited, such as in the setting of ischemia.

Entry via Fumarate

In addition to the amino acids phenylalanine and tyrosine entering as fumarate, the purine nucleotide cycle enriches the citric acid cycle based on the net reaction

Several workers have demonstrated that flux through the purine nucleotide cycle increases in skeletal muscle during intense exercise. This increased flux has two effects: first, it can maintain the pool of adenine nucleotides, and second, it can increase the citric acid cycle pool size via anaplerosis. Both of these effects are expected to improve energy metabolism in exercising muscle.

Figure 1 Cycles of energy transfer in heart muscle. The central role of the Krebs cycle is highlighted. See text for details.

Figure 2 Summary of anaplerotic pathways leading to the citric acid cycle. See text for details.

Exit of Cycle Intermediates: Balancing Anaplerosis

Under steady-state conditions, substrates entering the citric acid cycle via anaplerotic pathways are balanced by removing an equivalent amount of citric acid cycle intermediates through pathways that maintain a constant citric acid cycle pool size. These pathways have been termed cataplerotic, although the term is somewhat an oxymoron; instead, we prefer the more appropriate term drainage. Drainage pathways generally involve removing the citric acid cycle of cycle intermediates oxaloacetate (as aspartate via transamination, or phosphoenolpyruvate via decarboxylation by phosphoenolpyruvate carboxykinase (E.C. 4.1.1.32)), citrate via export from the mitochondrial matrix, or α -ketoglutarate via transamination to glutamate. While these drainage pathways are usually thought of as means to balance anaplerotic pathways, they play critical roles in renal gluconeogenesis and enterocyte energy production from glutamine (see below).

Measuring Rates of Anaplerosis

Changes in Citric Acid Cycle Pool Size

There are two principal methods for assessing anaplerosis based on changes in citric acid cycle pool size. The amount of citric acid cycle pool intermediates can be measured enzymatically or resolved with high-performance liquid chromatography. While both methods can reliably assess changes in the citric acid pool size, they do not provide insight into the pathways involved in anaplerosis nor do they determine relative rates of citric acid cycle enrichment from anaplerotic substrates. Furthermore, because anaplerosis is usually balanced by the exit of intermediates, changes in citric acid pool size are generally negligible.

Simply determining changes in citric acid cycle pool size provides no information on rates of anaplerotic flux or on specific anaplerotic reactions. Using substrates labeled with tracer ^{14}C and measuring incorporation into specific positions in citric acid cycle intermediates is more revealing. This method can determine rates of anaplerosis and is able to characterize the pathways involved in the process. However, the method is also laborious and prone to error. It requires sequential enzymatic degradation of intermediates quantifying the release of the ^{14}C label. This method has generally been replaced by ^{13}C -NMR spectroscopy or mass spectroscopy (NMR, nuclear magnetic resonance).

^{13}C -NMR/Mass Spectroscopy

^{13}C -NMR spectroscopy is used to assess quantitatively the relative contributions of various substrates to the citric acid cycle. This method determines the anaplerotic enrichment of individual carbon positions in citric acid cycle intermediates, similar to the radiotracer method discussed before, but without the need for digesting the carbon skeleton. ^{13}C -labeled compounds enter the carbon skeleton of citric acid cycle intermediates at specific positions through anaplerotic pathways or through dilution of ^{13}C by entry of unlabeled anaplerotic substrates. The enrichment of ^{13}C at those positions is then assessed and rates of anaplerotic flux are determined relative to rates of citric acid flux (a/c).

The method is illustrated in Figure 3 in which the enrichment of the carbon skeleton of α -ketoglutarate (and therefore glutamate, which is present in sufficient concentrations to be measurable by NMR spectroscopy) at the C-3 and C-4 positions is used to quantify anaplerosis. Label in these positions is generated from randomization of the C-4 carbon in the first turn of the citric cycle. Therefore, the sum of the ^{13}C enrichments of the C-2 and C-3 carbons will be equal to the enrichment of the C-4 carbon of glutamate. In contrast, with anaplerotic activity, the labeled C-2 and C-3 carbons will be diluted by ^{12}C carbons arising from unlabeled anaplerotic substrates, and the sum of the enrichments of the labeled C-2 and C-3 carbons will be less than the enrichments of the C-4 carbon of glutamate. For example, using $[2\text{-}^{13}\text{C}]\text{acetyl-CoA}$ as a substrate and conditions where there is no anaplerotic flux, analysis of the enrichment of C-2, C-3, and C-4 positions of glutamate reveals that $a/c = 0$, indicating no anaplerotic flux. Further refinements to the NMR-based methods take into account the recycling of carbons in pyruvate (a major source of anaplerotic substrate) derived from the citric acid cycle to improve the accuracy of measurements of anaplerotic flux.

Expression and Activity of Proteins Regulating Anaplerosis

The enzyme pyruvate carboxylase was discovered half a century ago, and over the last decade there has been much progress in understanding its structure and function. Using methods outlined above, studies have focused on changes in enrichment of citric acid cycle intermediates to assess the activity of anaplerotic pathways and explain changes in flux in terms of mass action and allosteric regulation of key enzymes. While this is most likely the case with acute changes in anaplerotic flux, changes in the expression and activity of enzymes responsible for anaplerosis must be taken into account when studying chronic processes such as pressure-overload-induced hypertrophy, heart failure, or diabetes. In streptozocin-treated diabetic rats, transcript levels of anaplerotic enzymes in heart and skeletal muscle are downregulated (Figure 4). Furthermore, mice with germline deletion of peroxisome proliferator-activated receptor- α show an increase in pyruvate carboxylase mRNA expression. Changes in transcript levels are paralleled by similar changes in protein expression. Although, the *in vitro* activities of the anaplerotic enzymes involved in the carboxylation of substrates (e.g., pyruvate carboxylase) can be measured by determining the incorporation of ^{14}C from $\text{H}^{14}\text{CO}_3^{-1}$, it is not known whether changes in expression correlate with changes in activity. However, in pressure overload-induced left ventricular hypertrophy in the rat, compensatory increases in anaplerotic flux into the citric acid cycle are accompanied by increases in transcript levels of malic enzyme.

Changes in Anaplerosis in Response to Environmental Stress: Workload, Nutritional Status, and Disease

Ultimately, any metabolic process has functional consequences, and anaplerotic pathways are no exception. Anaplerotic pathways play important roles in regulating a wide variety of organ responses to conditions of metabolic stress ranging from exercise to inborn errors of metabolism.

Anaplerosis in Skeletal Muscle during Exercise

The transition from rest to moderate or intense exercise is associated with large increases in skeletal muscle adenosine triphosphate (ATP) turnover, which must be supported by up to 100-fold increases in citric acid cycle flux. Although citric acid cycle intermediates increase only three- to fourfold, these relatively small increases in the citric acid cycle pool size (via anaplerosis) can reflect dramatic increases in citric acid cycle flux. It has been suggested that the increases allow skeletal muscle to adapt to the energetic demands of exercise, but interestingly, there is no appreciable change in citric acid cycle pool size at lower levels of exercise. The majority of changes in individual intermediates occur in the second span of the citric acid cycle (i.e., from succinate to oxaloacetate)

because the primary source of enrichment during acute exercise appears to be flux through the reaction catalyzed by alanine aminotransferase (E.C. 2.6.1.2). This reaction results in entry of glutamate as α -ketoglutarate; however, pyruvate carboxylase and malic enzyme may contribute minor amounts to citric acid cycle enrichment in exercising muscle.

Glutamine Metabolism by the Small Intestine

Glutamine is a source of energy for a number of specialized tissues, including the small intestine. When glutamine is taken up in the cell, it enters the citric acid cycle as α -ketoglutarate and leaves the cycle through oxidation as CO_2 . More specifically, α -ketoglutarate is converted to malate by citric acid cycle reactions and malate may be transported out of the

Figure 4 Expression of the biotin-containing carboxylases, acetyl-CoA (ACC), pyruvate carboxylase (PC), and propionyl-CoA carboxylase (PCC), in heart muscle based on streptavidin blotting (a) and pyruvate carboxylase expression in rat heart and skeletal muscle (b). Reprinted from Gibala MJ, Young ME, and Taegtmeyer H (2000) Anaplerosis of the citric acid cycle: Role in energy metabolism of heart and skeletal muscle. *Acta Physiologica Scandinavica* 168: 657–665.

mitochondria. In the cytosol, malate is converted to oxaloacetate. The malate–aspartate shuttle is bidirectional and can also transport electrons from extramitochondrial reduced nicotinamide dinucleotide (NADH) into the mitochondria or from intramitochondrial NADH to the cytosol.

Renal Ammonia Formation during Starvation

During starvation, when protein breakdown, renal gluconeogenesis and hepatic ketogenesis increase. Concomitantly, the rate of renal ammoniogenesis also increases. Ammonia is generated from amino acids, including glutamine, released by skeletal muscle. Glutamine is converted to α -ketoglutarate in renal cells. Alpha-ketoglutarate is metabolized to malate. Malate is transported out of the mitochondria, oxidized to oxaloacetate and to phosphoenolpyruvate, and ultimately used for gluconeogenesis. Although different from glutamine oxidation by enterocytes, this series of reactions also reflects the balance that is generally observed between anaplerotic and drainage pathways.

Ischemia and Substrate Level Phosphorylation

Early studies assessing cardiac metabolism by measuring arteriovenous differences in amino acid concentrations revealed that in patients with coronary artery disease and myocardial ischemia, the heart avidly extracts glutamate and releases alanine. This finding led to the hypothesis that the anaplerotic substrate glutamate enters the citric acid cycle as α -ketoglutarate via transamination with pyruvate (thereby forming the alanine that is released). Subsequently, the α -ketoglutarate is metabolized to succinate with the concomitant substrate level phosphorylation of guanosine diphosphate (GDP) to form guanosine triphosphate (GTP) (Figure 5). In this way, a span of the citric acid cycle can generate high-energy phosphates in the absence of sufficient oxygen for full citric acid cycle

Figure 5 Role of anaplerosis in improving myocardial energetics in the setting of ischemia (upper panel) or diabetic ketoacidosis (lower panel). Under both conditions, loss of cofactors ($\text{NAD}^+/\text{FAD}^+$ for ischemia, CoASH for diabetic ketoacidosis) inhibits full citric acid cycle activity. Anaplerotic pathways allow the citric acid cycle to work in spans, thereby increasing the production of high-energy phosphates. Modified from Taegtmeyer H and Passmore JM (1985) Defective energy metabolism of the heart in diabetes. *Lancet* 1: 139–141.

operation. Recent ^{13}C -NMR spectroscopic studies have demonstrated that during myocardial ischemia, the relative contribution of anaplerosis to citric acid flux may increase sevenfold compared to nonischemic conditions. Translational research based on the concept of this anaplerotic pathway has led to the development of glutamate-enriched solutions that increase the provision of anaerobic energy for the heart during coronary artery bypass surgery.

Insulin Secretion, Diabetes and Ketone Body Metabolism

Insulin secretion occurs through two mechanisms. The first is a process that involves closing of the cell-surface ATP-sensitive potassium channels in response to increases in the circulating glucose concentrations, which stimulates exocytosis of insulin-containing vesicles from the β -islet cells through an increase in the cytosolic calcium concentration. The second mechanism is dependent on pyruvate carboxylase, which is highly expressed in β -islet cells; it has been estimated that 35–45% of pyruvate enters the citric acid cycle through this anaplerotic pathway in β -islet cells. Inhibition of pyruvate carboxylase with phenylacetic acid decreases glucose-stimulated insulin release from β -islet cells. Furthermore, there is evidence that pyruvate carboxylase plays an important role in the early stages of type 2 diabetes. Specifically, in Zucker fatty rats with insulin resistance, the hyperfunctioning β -islet cells increase insulin production in part through increases in pyruvate carboxylase activity.

Citric acid cycle pool size increases in hearts of rats with experimentally induced diabetes, suggesting enrichment by anaplerotic pathways. We have suggested that an increase in anaplerotic flux, which primarily occurs through pyruvate carboxylation (via malic enzyme), plays an important role in maintaining flux through the second span of the citric acid cycle. Acutely, the metabolic derangement of ketoacidosis that occurs with diabetes inhibits flux through α -ketoglutarate dehydrogenase by sequestration of coenzyme A (CoASH). This phenomenon is associated with contractile dysfunction of the heart that can be readily reversed by the addition of glucose, lactate, or pyruvate (all of which are anaplerotic substrates). The effects of pyruvate are mediated by enrichment of malate in the citric acid cycle pool, which occurs by carboxylation of pyruvate to form malate and oxaloacetate through the actions of malic enzyme and pyruvate carboxylase, respectively (Figure 5). The citric acid cycle is thereby able to operate once again in a span that can generate reducing equivalents to support oxidative phosphorylation of adenosine diphosphate to form the ATP necessary to drive the contractile machinery of the heart.

Long-Chain Fatty Acid Oxidation Defects and Myopathies

The inability to oxidize long-chain fatty acids due to deficiencies in activity of carnitine palmitoyltransferase-1 (E.C. 2.3.1.21) or the enzymes involved in β -oxidation is associated with contractile dysfunction due to skeletal and heart muscle damage. One proposed mechanism responsible for the decrease in contractile activity is decreased citric acid cycle flux due to loss of intermediates from damaged myocytes. Based on this hypothesis, one clinical study has treated patients with defects in long-chain fatty acid oxidation with odd-chain triglycerides (which can increase the citric acid cycle pool size by entering as succinyl-CoA) and tested the hypothesis that an increase in citric acid cycle may improve muscle function. As proof of principle, the study has demonstrated beneficial effects such as reversing left ventricular dysfunction, decreasing muscle breakdown, and decreasing weakness. However, the effects of medium-length odd-chain fatty acids as potential anaplerotic substrates for the treatment of other forms of heart failure have not yet been assessed.

Pyruvate carboxylase deficiency is a rare autosomal recessive disease that affects a variety of organs, including the liver, kidney, brain, skeletal muscle, heart, and adipose tissue. The disorder is characterized by impaired gluconeogenesis, lactic acidosis, and, depending on the severity of the disease, neurologic manifestations ranging from minimal neurologic abnormalities to profound psychomotor retardation. In the most severe form of the disease, patients die within the first few weeks of life. Nutritional treatment of the disease with anaplerotic odd-chain triglycerides, such as triheptanoin, or aspartate has been shown to prolong life.

Summary and Perspective

Efficient energy transfer in the mammalian cell is linked to a series of moiety-conserved cycles, including the citric acid

cycle. Changes in the cell's environment lead to depletion and replenishment (anaplerosis) of citric acid cycle intermediates. The multiple pathways of anaplerosis utilize a variety of substrates, including carbohydrates, odd-chain fatty acids, and amino acids. These pathways reflect a system of redundancy that is important for both function and survival of the cell.

Angiotensin II Peptide hormone derived from angiotensinogen.

Cardiovascular effects Effects on the heart and blood vessels.

Receptor Hormone-binding protein.

Receptor signal Reaction emitted from the receptor upon hormone binding.

Angiotensin (Ang), initially considered as a major pressor substance, is now recognized to mediate numerous physiological and pathophysiological functions. Over the past 70 years, four different active forms of angiotensins, Ang II, Ang III, Ang IV, and Ang (1–7), have been identified. The complexity of their action was multiplied by subtypes of their respective receptors, AT_{1A}, AT_{1B}, and AT₂ for Ang II, AT₄ for Ang IV, and Ang (1–7) receptors (Table 1). Each subtype of the receptors shows more than one signaling mechanism. This article presents an overview of the formation and the structure of angiotensins, the receptors of Angs, and the representative signaling pathways, which play very colorful regulatory functions covering wide areas such as vasoconstriction, vasorelaxation cardiovascular hypertrophy and remodeling, atherosclerosis, thrombosis, stimulation of mineralocorticoid synthesis, reactive oxygen species (ROS) formation and release, facilitation of sympathetic outflow, renal electrolyte metabolism, control of central nervous system in water-drinking behavior, blood-pressure regulation, memory retention, growth-inhibition apoptosis, tissue differentiation, arachidonic acid and prostaglandin formation, and regulation of insulin signals.

Angiotensins (Ang) Structure and Formation

Angiotensin I

All angiotensins are derived from the amino terminus of the ~65 kDa prohormone angiotensinogen, via a series of proteolytic cleavage by a variety of proteinases and peptidases. The enzyme that initiates this process is renin. This aspartyl protease is active in pH 6–7, reacts exclusively with angiotensinogen, and cleaves only one singular leucyl peptide bond of the prohormone between residues 10 and 11 generating the decapeptide Ang I (Figure 1). Ang I is hormonally inactive; thus, it is prohormone as it has no specific receptor to transmit its signal. The physiological significance of Ang I is that it appears to confer a high degree of specificity to the angiotensin-generating system in plasma or in the intracellular system in which there are numerous proteins.

Angiotensin II

The inactive Ang I is activated to active Ang II by the metallo-endopeptidase, angiotensin I converting enzyme (ACE), which

is identical to kininase II. This enzyme was the target for the first most successful drugs for the treatment of renin-dependent hypertension, with a minimum of side effects and complications. Starting with captopril, a series of long-acting ACE inhibitors were synthesized and were found to almost completely block Ang II formation. Ang II has two subtypes of receptors, AT₁ and AT₂. The heptapeptide Ang III is the product of amino terminal cleavage of Ang II by aminopeptidases. Although Ang III is prominent in the neuronal system, it shares receptors, AT₁ and AT₂, with Ang II. The amino-acid sequence of rat AT₁ and AT₂ are shown in Figure 2.

Ang (1–7)

Ang (1–7) can be formed mainly from Ang I by the successive removal of the C-terminal Leu by ACE2 then the dipeptide Phe-His by Ace. It can be formed from Ang II by ACE 2 (Figure 1). It has been shown to activate phospholipase A₂ to release arachidonic acid from phospholipids leading to the formation of prostaglandins.

Ang IV

Ang IV is the hexapeptide Ang (3–8). It was reported to stimulate the production of plasminogen activator inhibitor to stabilize blood clots and to promote atherosclerosis. Other roles in the brain have also been reported.

Whereas receptors for Ang II, Ang III, and Ang (1–7) are G-protein-coupled receptors, the receptor isolated and cloned from the adrenal membranes is a single transmembrane type.

Angiotensin Receptor

Ang I-Binding Protein

Despite the ubiquitous distribution of Ang I-binding proteins, no physiological function was found for it.

Ang II Receptors

Receptor subtypes

Synthesis of a series of variants of Ang II revealed the presence of an Ang II receptor, confirming the earlier finding that there are two types of Ang II receptors, one resistant to dithiothreitol

Table 1 Angiotensin

Angiotensins	Receptors	G-proteins coupled
Ang II	AT _{1a}	G _{q/11} , G _i , G _{12/13}
	AT _{1b}	G _{q/11} , G _i , G _{12/13}
	AT ₂	G _i
Ang III	The same as Ang II	The same as AT ₁ and AT ₂
Ang (1–7)	<i>Mas</i> oncogene product	?
Ang IV	AT ₄ /IRAM	Single transmembrane receptor

and the other sensitive to the treatment. Inactive variants of Ang II were synthesized to obtain Ang II receptor antagonists. These inhibitor peptides also showed the importance of Arg², Tyr⁴, and Arg⁸ for type 1 Ang II receptors. Particularly, replacement of Phe⁸ to Ile, Thr, or Ala (saralisine) greatly reduced Ang II receptor signals, such as Ca²⁺ response, although binding is not significantly affected. However, these peptidic analogs were partial agonists. These peptidic inhibitors did not distinguish two different receptors, AT₁ and AT₂. It was only after the syntheses of nonpeptide inhibitors that indications were obtained for the presence of at least two receptor subtypes for Ang II, which differ in biochemical and physiological responses, localization, and ontogeny.

Figure 2 Rat angiotensin receptor AT_{1A} and AT₂.

Direct proof for the two major receptor subtypes, AT₁ and AT₂, were provided by expression cloning of their cDNAs from rat and bovine tissues. Rodents were found to have three genes: AT_{1a}, AT_{1b}, and AT₂. It is likely that birds, reptiles, and amphibians may also have more than one type of receptor. Rat or mouse murine AT_{1a} and AT_{1b} share a 98% amino acid sequence identity through their respective genes and are located in different chromosomes. They can be distinguished only by Northern blot analysis or *in situ* hybridization of 3' noncoding sequences, where a sizeable difference occurs in nucleotide sequences. In contrast, AT₁ and AT₂ share only 34% amino acid sequence homology. Noteworthy is the localization of the AT₂ gene in the X chromosome throughout species.

AT₁ receptor signaling

Most of the signal responses considered earlier as Ang II actions seem to be mediated by AT₁. These responses are smooth muscle contraction and hypertension, mineralocorticoid synthesis, tyrosine hydroxylase gene expression in adrenal and central and peripheral adrenergic facilitation, stimulation of cellular hypertrophy, mitogenesis and migration, plasminogen activator synthesis, stimulation of fibrosis, renal sodium retentions, centrally regulated dipsogenesis, hypertension, and generation of ROS. The major AT₁ signaling pathways are mediated by the Gq/11-mediated phospholipase β_1 activation via cellular [Ca²⁺] increase and protein kinase activation. However, AT₁ can also couple to Gi and G_{12/13}.

It is now well accepted that AT₁ can also activate pathways that involve tyrosine kinase activation, such as epidermal growth factor (EGF) receptor through Ca²⁺-stimulated heparin-binding EGF, and consequent activation of Ras, ERK 1/2, which further results in p70^{S6K} and phosphatidyl inositol-3-kinase and activation of immediate early gene pathways. AT₁ also activates the JAK-STAT system, Src family kinases, tyrosine phosphatase SHP-2, PLC- δ , JNK, and p38 MAP kinase. Accumulating lines of evidence seem to support the idea that some of these tyrosine kinase pathways do not involve G-proteins, based on results of mutagenesis studies that eliminate key residues required for interaction of cytoplasmic loops of AT₁.

Importantly, many of the tyrosine kinase activation steps are activated by the ROS, such as superoxide anion and hydrogen peroxide. The formation of superoxide anion is mediated by NAD(P)H oxidase, which is activated by Ang II. Important recent additions to the knowledge of Ang II-mediated smooth muscle contraction are the Rho-Rho kinase system. This information is of particular significance for the mechanism of hypertension. On the other hand, cardiovascular hypertrophy and remodeling of resistance vessels are other important aspects for cardiac failure and diminished vascular compliance and hypertension.

AT₂ receptor signaling

Studies on AT₂ signaling, particularly using cultured cells, were not straightforward because of the rapid disappearance of AT₂ receptor during repeated passage of cells and exposure to growth medium. Interpretation of results was also difficult because of rapid ontogenic change in AT₂ expression, particularly postnatal decline and increase under stress, during tissue repair or inflammation. *In vivo* studies eliminate many of these difficulties. Thus, *in vivo* studies of loss of function of AT₂ in the

kidney, vasculature, heart, and brain, and particularly adrenal and colon, where AT₂ remains expressed in adults, are producing substantive results.

In vitro studies on AT₂ receptor signals

Although AT₂ (the AT₂ receptor) is labile in cells in growth-culture medium, some cells, such as PC12w, N1E115, and R3T3, maintain AT₂ expression, but not AT₁, over several generations. Ang II stimulation resulted in growth inhibition via either MAP kinase phosphatase or the tyrosine phosphatase SHP1 even inducing apoptosis, but not all AT₂-expressing tissues or cells undergo apoptosis. Ovarian atretic cells express AT₂ prominently, yet Ang II treatment failed to induce apoptosis. AT₂ expressed in neuronal cells activate Ser/Thr phosphatase PP2A via a Gi-coupled mechanism and was reported to open delayed rectifier K⁺ channel, a hyperpolarizing mechanism. Its growth inhibitory mechanism on endothelial cells was shown to involve the following sequence of events:

Lowering pH → release of cytoplasmic kallikrein
→ generation of bradykinin → activation of NOS

This can explain relaxation or dilation of resistance arteries *ex vivo* by AT₂ and its reversal by its specific synthetic inhibitor PD123319 or PD123177, and relaxation by AT₂ partial agonists CGP24112. Although AT₂ was shown to bind specifically with G α_2 or G α_3 , not all of these growth-suppressing or cGMP-mediated signals were inhibited by pertussis toxin.

In vivo studies on AT₂ signals

AT₂ gene-deleted mice and AT₂ inhibitor-treated mice were shown to slowly retain Na and show impaired natriuresis and markedly diminished urinary cGMP, presumably by the mechanism analogous to endothelial cells discussed above. These observations seem to indicate that the signals mediated presumably by inhibition of phosphatases work in the direction opposite to the growth-stimulating signal of AT₁. However, paradoxical observation exists in which AT₁ and AT₂ function in parallel. An increasing number of publications reported that chronic infusion of the AT₂-specific blocker PD123319 was able to inhibit chronic Ang II-induced aortic smooth-muscle hypertrophy and fibrosis despite continuously elevated blood pressure. Despite a short half-lifetime of PD123319 *in vivo*, chronic infusion by osmotic mini-pump suppressed the Ang II-infused aortic hypertrophy. AT₂ gene-deleted mice also showed marked resistance against left ventricular hypertrophy induced by pressure overload or chronic Ang II infusion. Another example of parallel phenotypic effect of AT₁ and AT₂ was found in stimulation of tyrosine hydroxylase by both AT₁ and AT₂ in adrenal chromaffin cells *in vivo*.

Since all of the paradoxical results were obtained under well-controlled conditions, signaling mechanisms in specific tissues were investigated. It was found that the AT₂ binds a zinc finger protein and serves as a transporter to deliver the zinc finger protein to the nucleus, which activated transcription of phosphatidyl inositol 3-kinase p85 α subunit (p85 α PI3K). This triggers a subsequent cardiac hypertrophic pathway. These results indicate that the AT₂-mediated cardiac hypertrophy uses signals distinct from those which are activated by AT₁. The parallel phenotypic results were due to tissue

specific expression of the zinc finger protein in the heart but not in the kidney, where the AT_2 signal depends on the kallikrein–NOS–cGMP mechanism. In contrast, the cardiac tissue uses a more direct activation mechanism of nuclear transcription of p85 α PI3K. The p85PI3K activation has been shown to induce a variety of cardiac hypertrophy mechanisms.

Major Physiological Roles of AT_1 and AT_2

Targeted gene deletion of AT_{1A} , AT_{1B} , or angiotensinogen in mice showed that angiotensin II has a profound effect on the maintenance of blood pressure; dual deletion of AT_{1A} and AT_{1B} resulted in hypotension by 45–50 mmHg and no pressor response to Ang II infusion. AT_{1B} was responsible for only 10% of the pressor effect. Interestingly, these animals showed profound defects in the renal papillary and medullary formation suggesting defects in Na reabsorption, an idea in agreement with the polyurea and increased Na excretion. These animals were stunted and it was difficult to keep them alive without daily saline injection. AT_2 gene deletion did not cause overt physical deficiency. However, closer examination revealed that AT_2 -deficient mice show high frequency (28% penetrance) of uretero-renal pelvis ligation that is closely analogous to a human neonatal disease called Kakkut syndrome. Connection to the ureter of the renal pelvis is the last step of the kidney morphogenesis and AT_2 concentration is seen in the renal pelvis at this stage in a normal fetus.

Recently, Srivastava's group reported a very intriguing observation in which they identified families with severe mental retardation and traced their gene defect to the absence or 'mis-sense' mutation of AT_2 gene on the X chromosome. Thus, AT_2 function is not only limited to the renal, adrenal, and cardiovascular system, but brain function also depends on AT_2 . Indeed, AT_2 gene-deficient mice show a pattern of fearful behavior.

Angiotensin (1–7)

Functions

Ferrario and his associate reported physiological functions of Ang (1–7). Since the heptapeptide seemed to be generated by one step of carboxypeptidase, it was not clear whether it was a part of Ang II function. However, it was shown that Ang (1–7) is generated from Ang I by an ACE2 and ACE as in the updated [Figure 1](#). Since the affinity of the heptapeptide binding to the brain plasma membrane was in the nanomolar range, it seemed to have a physiological significance. Its specific action was shown as arachidonate release and prostaglandin synthesis. Its systemic presence and function were also demonstrated. Decisive evidence of Ang (1–7) as a hormonal peptide came as the receptor was identified.

Ang (1–7) receptor

In 1988, Hunley and colleagues presented the hypothesis that *Mas* oncogene product was the Ang II receptor. This hypothesis failed to meet the test of many investigators. AT_1 and AT_2 were cloned soon afterward as unmistakable Ang II receptors. However, the *Mas* oncogene story made a full circle recently when Santos, Walther, and their collaborators showed that the *Mas* oncogene product expressed in COS7 cells binds Ang (1–7) with a nanomolar K_D value and releases

prostaglandins in an abstract form. It has a structural feature of a seven-transmembrane-domain receptor. Further details are awaited.

Ang IV

Harding and colleagues showed that the hexapeptide Ang IV binds to receptors in a variety of tissues and increases blood flow. Recently, Xie, Mendelsohn, and their collaborators purified Ang IV receptor from adrenal plasma membrane and succeeded in cloning the cDNA. They found that it is identical with insulin-regulated amino peptidase (IRAP) with a single transmembrane domain. Its possible interaction with insulin is of potential interest as an interface between angiotensin and insulin. However, Ang IV is not the only ligand that binds the extracellular domain. LVV hemorphin, a segment of hemoglobin, was also reported to be a binding ligand. AT_4 is expressed heavily in the hippocampus and signals to stimulate acetylcholine. Its potential role in memory retention is of great interest in relation to a possible regulatory role of this aminopeptidase. Ang II also was shown to be involved in the regulation of long-term potentiation (LTP). Thus, the roles of angiotensin are not limited to the control of blood pressure, water drinking, and dipsogenesis in the hypothalamus and brain stem. AT_4 expressed in hippocampus, AT_2 expressed in central amygdala nucleus, and Ang II stimulation of LTP, point to the roles of angiotensins in normal cortical function.

AT_3

We reported non- AT_1 –non- AT_2 Ang II receptors in neuro 2A cells were expressed at room temperature, but not at 37 °C. Therefore, we consider it as a likely product of mycoplasma that infected the neuro 2A cell line we used. Thus, at present, AT_3 is not of mammalian origin.

Glossary

Anorexigenic Feeding inhibitory.

Cephalic Actions stimulated by the site, smell, and taste of food prior to contact with gastrointestinal sites.

Orexigenic Feeding stimulatory.

Satiation Negative feedback process stimulated by ingested food to inhibit eating.

Satiety State of satisfaction following ingestion.

Introduction

There are many inputs from the periphery to the brain providing information regarding the energy status of the body. Energy intake is registered through taste receptors, via distension of the stomach, and through nutrient-induced alterations in the release of gut hormones that potentially affect energy intake, either acutely or over the longer term. These gut hormones generally act in the hindbrain through either vagal afferents or directly, and by altering neuronal activity in the hypothalamic appetite centers. The first gut hormones were discovered more than 50 years ago; yet, the function and potential of these peptides in modulating energy balance is not completely clear, and the picture gets more complex as new hormones are discovered. In this article is provided a brief introduction to the most thoroughly studied gut hormones in relation to satiety and food intake.

Anorexigenic Gut Hormones

Cholecystokinin

Cholecystokinin (CCK) is a peptide produced throughout the gastrointestinal tract, but especially in the enteroendocrine I cells of the duodenum and jejunum. It is secreted in response to the presence of nutrients in the gut lumen. Fatty acids containing more than a 12-carbon chain are particularly effective in stimulating CCK secretion. The anorexic effect of CCK, which was first discovered by Gibbs and colleagues in 1972, has been the most-studied feeding effect of any gut peptide and in many ways has become the model against which the effects of other gut peptides are measured. Exogenous CCK administration results in dose-dependent reductions in food intake across multiple species, including man, and in multiple testing situations. CCK-induced reductions in food intake can occur without reported side effects. Meal-contingent CCK administration results in reductions in meal size and repeated meal-contingent administration continues to reduce meal size, but results in a compensatory increase in meal frequency such that overall food intake is unchanged.

Roles for CCK1 (also called CCK A receptors) in the pyloric sphincter and on vagal afferent fibers in the satiety action of CCK have been suggested. These receptors are also widely distributed in brain areas such as the nucleus tractus solitarius area postrema (AP), hypothalamic ventromedial nucleus and dorsomedial nucleus sites at which central CCK may also affect food intake.

In rats and nonhuman primates, antagonism of the CCK1 receptor blocks the satiating effect of exogenous CCK, and, when given alone, CCK1 receptor antagonists increase meal size and in some situations, overall food intake. Results of assessments of the satiety actions of endogenous CCK in human studies have been mixed. CCK doses that lead to a plasma CCK peak of similar magnitude as seen with meal-stimulated release have had mixed effects on food intake, but have resulted in reliable changes in reports of decreased hunger and increased fullness. Another approach clearly supports CCK's role as a satiety factor in humans. Intraduodenal perfusions of long-chain fatty acids lead to reduced calorie intake and increase in plasma CCK concentration. Administration of the CCK1 receptor antagonist lorglumide intravenously at the same time as the intraduodenal infusion abolishes the satiety effect. Further implicating physiological relevance of CCK in satiety is the impaired meal stimulation of CCK secretion in bulimic patients.

The importance of the CCK1 receptor is also seen in the Otsuka Long Evans Tokushima Fatty (OLETF) rat, which completely lacks this receptor. Early on, these rats develop obesity, hyperglycemia, and impaired glucose regulation that progresses into noninsulin-dependent diabetes and finally into severe insulin-dependent diabetes. The same phenotype is not seen in the CCK1 receptor knockout (KO) mice, indicating species differences or that an additional impairment may be implicated in the phenotype seen in the OLETF rats.

Peptide YY

Peptide YY (PYY) is a member of the family of peptides that includes neuropeptide Y (NPY) and pancreatic polypeptide (PP). There is about 70% homology among the three peptides and the peptide sequences are highly conserved between species. Furthermore, they have the same tertiary structure, namely the characteristic PP fold consisting of an extended pyroproline helix and an α -helix held together by β -turns. All three peptides have been associated with food intake.

PYY is expressed in the enteroendocrine L-cells primarily in the ileum and colon. These cells also express glucagon-like peptide-1 (GLP-1) and oxyntomodulin (OXM). PYY binds with high affinity to all Y-receptor subtypes but PYY is cleaved by dipeptidyl peptidase yielding the circulating acid form of PYY referred to as PYY₃₋₃₆. PYY₃₋₃₆ binds with high affinity to Y₂ but with lower affinity to Y₁ and Y₅ receptors.

The plasma concentration of PYY₃₋₃₆ increases shortly after nutrient intake and even before nutrients reach the PYY-producing cells. The plasma levels peak around 90 min after meal initiations, and in contrast to the more short-term acting peptides, such as CCK, the levels stay elevated for up to 6 h.

Intravenous administration of PYY₃₋₃₆ to normal weight and obese human subjects has effects on appetite resulting in up to 30% decrease in food intake. The reduction in calorie intake is accompanied by a reduction in subjective hunger scores. After the infusion is stopped, the anorectic effect has been observed to last for up to 12 h, even after plasma PYY₃₋₃₆ returns to normal levels.

The decrease in food intake that is seen when administering PYY peripherally is considered to be mediated both through delayed gastric emptying and by changes in central feeding circuits. In the arcuate nucleus of the hypothalamus, PYY₃₋₃₆ leads to inhibition of the orexigenic AgRP/NPY-neurons by binding to presynaptic Y₂ receptors.

The actions of endogenous PYY in inhibiting feeding remain to be completely determined. When infusing PYY intravenously in human subjects, in amounts resulting in peak concentrations comparable to the physiological peak seen after meal initiation, no effect on food intake and satiety has been obtained. Furthermore, although Y₂ antagonists have been shown to block the feeding inhibitory actions of exogenous PYY, they have not been shown to increase food intake when given alone. This does not rule out that PYY is an anorectic hormone, but it may imply that the physiological effect of PYY should not be considered alone. GLP and PYY are cosecreted following meal initiation. Co-administering these peptides in low concentrations has an effect on food intake, which is not seen when giving either peptide separately at the same dose. This additive effect has been observed in both rodents and humans.

Apolipoprotein A-IV

Apolipoprotein A-IV (APO-IV) is primarily synthesized in the small intestine, where secretion is stimulated by lipid absorption. Plasma APO-IV level peaks 15 min after fat ingestion and the level remains elevated for about 3 h. In rodents, there is a circadian fluctuation of plasma APO-IV determined by the pattern of food intake with highest levels in the beginning of the dark phase.

During prolonged ingestion of a high-fat diet, APO-IV levels increase in both human and rat. APO-IV is also produced within the hypothalamus, and intracerebroventricular (ICV) administration of APO-IV antibody initiates food intake, leading to the suggestion that APO-IV affects food intake by inhibiting meal initiation rather than affecting meal size.

Supporting a physiological satiety role of APO-IV is the dose-dependent decrease in food intake seen when administering the protein both through the central and the peripheral route. This effect is seen with doses in the physiological range.

Incretins

The incretins are a group of anorexigenic hormones defined by their ability to stimulate glucose-dependent insulin secretion and by the fact that they are released in response to nutrient

intake. This phenomenon was originally discovered through the observation that more insulin is secreted after oral ingestion of glucose than after intravenous glucose injection. Therefore, something in the gut was thought to be involved. The two most important hormones in this group are GLP-1 and gastric inhibitory polypeptide (GIP).

Glucagon-Like Peptide-1

There are several tissue-specific cleavage products of the proglucagon mRNA. In the intestine and brainstem, the cleavage results in OXM, glicentin, GLP-1, and GLP-2 whereas in the pancreatic α -cells the major product is the glucagon hormone. The differential production of the gene products is regulated by tissue/cell-specific expression of prohormone convertases 1 and 2.

GLP-1 is a potent incretin. Administration of the hormone leads to decreased glucose levels and augmented glucose-stimulated insulin release in diabetic patients. GLP-1 directly stimulates insulin release and increases β -cell glucose sensitivity both by binding to GLP-1 receptors on the β -cells and by indirect neural activation.

The active forms of GLP-1 consist of 29–30 amino acids either as the amidated form GLP-1 (7–36) amide or as the glycine-extended form GLP-1 (7–37), which is the most abundant form in humans. GLP-1 is secreted throughout the gastrointestinal tract from L-cells predominantly in the distal part of the jejunum, ileum, and the colon. Basal fasting human GLP-1 plasma levels are around 5–10 pM. The level increases in response to meal ingestion, and the first increase is observed within 15 min of meal initiation and peaks within 60–90 min. After peaking, the level quickly returns to basal. The magnitude of the rise in plasma GLP-1 follows the amount of calories ingested and the composition of the meal. The protease dipeptidyl peptidase-IV (DPP-IV) cleaves peptides that have an alanine at position 2. This leads to very short half-lives of systemic active GLP-1, GLP-2, and OXM of less than 7 min.

A direct central role of GLP-1 in feeding control is plausible as GLP-1 binds to several brain areas involved in food intake, and injection of GLP-1 directly in the paraventricular nucleus (PVN) has been shown to decrease food intake in rats. The central binding and activation could be mediated through activation of GLP-1 production in the neurons within the hypothalamus.

Several studies indicate that systemic GLP-1 acts to affect food intake through peripheral GLP-1 receptors. An anorexic effect is seen with peripheral administration of the combined GLP-1-albumin protein that does not cross the blood–brain barrier (marketed as Liraglutide). The effect of peripheral GLP-1 could be mediated via the vagal nerve as GLP-1 increases firing of vagal afferents and this increased firing is inhibited by exendin 9–39. In addition, high expression of GLP-1 receptors in the nodose ganglion and vagal terminals supports vagal signaling.

Studies using the competitive GLP-1 receptor antagonist exendin 9–39 confirm that the effect of GLP-1 on feeding may be partly central and partly peripheral mediated. Systemic administration of exendin 9–39 prevents the anorexic effect of systemic GLP-1. The same is the case for the central route where ICV injection of exendin 9–39 inhibits the anorexic effect of ICV GLP-1. However, central exendin 9–39 does not prevent the anorexic effect of systemic GLP-1, supporting distinct pathways. Disruptions of vagal signaling have been shown to

decrease the anorexic effect of the peripheral GLP-1, further supporting dual mechanisms.

Exogenous delivery of GLP-1 induces satiety and decreases food intake in normal weight, obese, and diabetic humans without any side effects. This effect is sustained with lower physiologically relevant doses. The anorectic effect of the hormone is abolished by administration of exendin 9–39, which will even lead to increased food intake under certain circumstances. These data suggest that GLP-1 is a physiological regulator of satiety and food intake.

The short half-life of GLP limits the therapeutic potential of the hormone itself. Effort has therefore been put into developing long-acting GLP-1 agonist, and this enables to not only decrease glucose levels in diabetic patients but also decrease food intake and body weight. Liraglutide has been shown to decrease body weight when administered daily in humans and the first longer-lasting GLP-1 analog (exendin-4) is available in the market for diabetes treatment (Exenatide).

Oxyntomodulin

OXM consists of 37 amino acids including the entire sequence of glucagon with the addition of a basic C-terminal extension, the so-called 8-amino-acid spacer peptide-1. OXM got its name because the first effect seen of the peptide was the inhibition of the oxyntic glands of the stomach. OXM is co-released postprandially with GLP-1 and PYY from intestinal L-cells. An anorectic effect of OXM was discovered when the hormone was peripherally administered to rodents, and this effect has been reproduced in humans. The effect is blocked by prior injections of the GLP-1 receptor antagonist exendin 9–39 and the effect is lost in GLP-1 receptor KO mice.

Similar to GLP-1, OXM is an incretin although not as potent as GIP and GLP-1. This correlates with the lower affinity of OXM for the GLP-1 receptor. In contrast, the anorectic properties of OXM are as potent as those of GLP-1, indicating that separate mechanisms are involved in the incretin and feeding effects of the peptide. Part of the anorexic effect of OXM is explained by 20–40% decrease in ghrelin levels that may be measured after OXM administration in both rodents and humans. Moreover, increased energy expenditure following administration contributes to the weight loss seen in humans.

Central pathways could be involved in the anorexic effects of OXM as it increases release of anorexic neuropeptide α -melanocyte-stimulating hormone from hypothalamic explants, and direct injections of OXM into the PVN affects food intake. This action is likely to occur through the GLP-1 receptor as exendin 9–39 administration into the arcuate nucleus has been shown to prevent the OXM-mediated decrease in energy intake.

The physiological plasma level of OXM is increased in gastric bypass patients. This may be part of an overall gastric hormonal shift, which could contribute to the fast weight loss and improved glucose regulation seen in these patients.

Gastric Inhibitory Polypeptide

GIP is a 42-amino-acid gastrointestinal hormone. It is a member of the incretin family mediating increases of insulin secretion prior to the postabsorptive nutrient-induced increase in blood glucose. GIP is secreted primarily from the stomach and

the duodenum K cells in response to ingestion. The release follows the rate of intake and absorption of, especially, fat and glucose. GIP is also a substrate for DPP-IV cleavage leading to a very short half-life of the active peptide of only 5–7 min. Besides the incretin effect of GIP, it has also been shown to enhance fatty acid synthesis and triglyceride storage in adipocytes. Administration of GIP does not have an acute effect on food intake, nor does the KO of the receptor. However, GIP receptor KO mice are protected against diet-induced obesity and have reduced fat mass. Together with data demonstrating that GIP KO mice have increased energy expenditure, this suggests a physiological role of GIP in maintaining long-term energy homeostasis.

Pancreatic Peptides

Pancreatic Polypeptide

PP is secreted by specific cells in the pancreatic islets. The amount of peptide released is dependent upon calorie intake and the composition of the meal. Peripheral infusion of PP reduces food intake only after 2 h and the effect is prolonged over the following 24 h in humans. The same effect is seen after peripheral administration in rodents, while central administration increases food intake. These contradictory effects, which are also seen with PYY, may be caused by differential stimulation of the Y-receptor subtypes. PP does not seem to cross the blood-brain barrier and the anorexic effect is believed to be largely mediated through vagal or circumventricular organ sites. After peripheral administration, autoradiography studies have shown accumulation of PP in AP. This area has a high expression of Y_4 receptors, suggesting that the anorectic effect of PP is mediated by this receptor. Similar to the Y_2 receptors, the presynaptic Y_4 receptors in the brain have an autoinhibitory effect on NPY neurons. A role for the vagus is also supported by studies showing diminished anorexic effect of peripherally administered PP in vagotomized animals, and further by a high concentration of Y_4 receptors in the dorsal vagal complex, the site of central vagal afferent terminations. The role of endogenous PP in feeding control is yet to be investigated.

Glucagon

The most prominent role of glucagon is to stimulate glycogenolysis and gluconeogenesis to maintain euglycemia during fast or in the mode of rapid energy expenditure. However, glucagon is also released from the pancreatic α -cells when food is ingested. The meal-related glucagon release is brief and initiated within the first few minutes of meal initiation. This is most likely cephalic stimulated. The rise in systemic glucagon is modest but the portal-vein glucagon concentration can be relatively high without change in overall systemic levels.

Exogenous glucagon reduces food intake most efficiently and is dose dependent when administered through hepatic portal infusion. These infusions decrease meal size without affecting overall meal number in rodents and humans, and do so at physiological concentrations. The feeding effect is prevented by afferent vagotomy. Intraperitoneal and hepatic portal injection of a specific polyclonal glucagon antibody increases meal size and hepatic glucose output suggesting a

role for endogenous glucagon in feeding control. This effect is not seen when injected in the vena cava, suggesting that the feeding effect of glucagon is mediated in the liver.

Insulin

The most prominent function of insulin is mediating glucose uptake in peripheral tissues and thereby maintaining euglycemia. The level of insulin is low during fasting. During and after a meal, insulin is released in a biphasic manner. Insulin also acts as an adiposity factor with basal levels being correlated with body fat. Insulin is transported across the blood–brain barrier and there is a high concentration of insulin receptors in the arcuate nucleus of the hypothalamus. In addition, insulin increases the brain's sensitivity to other satiety factors and thereby relates body adiposity to food intake. ICV insulin injection reduces food intake in a dose-dependent manner and insulin antibodies have the opposite effect leading to increased food intake.

Amylin

Amylin is cosecreted with insulin from the pancreatic β -cells. Similar to insulin, amylin levels are low during fasting and increase quickly during eating, in proportion to the meal size. The overall level of amylin is also proportional to the amount of body fat. Exogenous systemic delivery of amylin, prior to a meal, decreases meal size in rats. This is mediated through activation of amylin-binding sites in the AP, which are accessible through the relatively permeable blood–brain barrier of this circumventricular organ. Evidence for an AP site of action also derives from lesions studies demonstrating that AP lesions prevent the anorexic effect of exogenous systemic amylin. Actions in other brain areas are also implicated as low-dose ICV amylin produces potent long-lasting decrease in feeding. Supporting a physiological role for amylin in feeding control are data demonstrating increase in food intake in response to amylin receptor antagonism.

Enterostatin

Procolipase is synthesized and released from the pancreas in response to lipid intake. In the intestinal lumen, procolipase is cleaved to active colipase and enterostatin. Enterostatin is a 41-amino-acid protein and part of the sequence is highly conserved in mammal species. Plasma enterostatin increases significantly after ingestion of a lipid-containing meal. Exogenous administration of enterostatin reduces food intake and especially the intake of fat or high-fat foods. An iv dose of enterostatin giving a similar rise in plasma enterostatin to that found after ingesting a high-fat meal inhibits food intake, thereby supporting a physiological function. An inhibition of food intake is also obtained when administering the peptide ICV.

Orexigenic Gut Hormone

Ghrelin

Ghrelin is a 28-amino-acid enteric peptide. It is a natural ligand for the 7-trans-membrane growth hormone secretagog

receptor (GHS-R 1a), also known as the ghrelin receptor. The acylation of the third residue is necessary for ghrelin to activate the ghrelin receptor and for the peptide to cross the blood–brain barrier. The acylation is catalyzed by the gastric enzyme ghrelin O-acyltransferase. Eighty to ninety percent of circulating ghrelin is in the nonacylated form, which is not able to bind to and activate GHS-R 1a, and therefore has no effect on growth hormone release and food intake.

Ghrelin is mainly secreted from X/A-like cells in the oxyntic glands of the gastric fundal mucosa, but it is also present in the bowel, especially the small intestine with decreasing density of ghrelin-positive cells from the stomach throughout the gut.

There are diurnal changes in ghrelin levels in humans and rodents. During fasting, levels are high with a peak just before meal initiation and then a decline after food intake, mediated by the presence of nutrients in the gut. The postprandial suppression of ghrelin is proportional to the load of ingested calories. Ghrelin levels not only change in response to acute changes in nutritional status but also are affected by chronic metabolic changes (obesity, etc.). Fasting plasma ghrelin levels are lower in obese subjects compared to normal weight subjects, while subjects with low body mass index (BMI) (such as patients suffering from anorexia nervosa or cachexia) have elevated ghrelin secretion. These abnormalities in ghrelin secretion are reversed upon normalization of body weight. The only known exception to this negative correlation between ghrelin level and BMI is in the Prader–Willi syndrome, where obesity is correlated with hypersecretion of ghrelin.

Currently, ghrelin is the only peripheral hormone known to stimulate food intake. Peripheral administration of ghrelin increases feeding in rodents and humans, and continuous administration increases body weight, not only through hyperphagia but also through increased lipogenesis and decreased energy expenditure.

Ghrelin's feeding stimulatory actions are thought to depend on ghrelin binding to hypothalamic NPY/AgRP neurons and increasing the activity of these orexigenic neurons by a direct presynaptic effect. This binding simultaneously has an inhibitory effect on proopiomelanocortin neurons mediated by increased frequency of spontaneous GABA-ergic inhibitory postsynaptic currents, leading to a decrease in the spontaneous activity of these anorexigenic neurons. Ghrelin can access the brain via areas not protected by the blood–brain barrier and by transport across the barrier. Furthermore, a lesser production of ghrelin within the hypothalamus is possible, as mRNA has been detected there.

There is no clear evidence showing that the orexigenic effect of ghrelin is vagally mediated. However, the ghrelin receptor is expressed in the nodose ganglion and transport to the nerve terminal has been described, indicating that vagal afferents may be involved in mediating some of ghrelin's other functions.

Chronic administration of ghrelin-receptor antagonists leads to a reduction in food intake and a reduction of body weight in normal weight and diet-induced obese rodents supporting a role for endogenous ghrelin in feeding control. In ghrelin and ghrelin-receptor KO mice, there is a shift in

preferred energy substrate toward fat, and these mice are resistant to early onset diet-induced obesity.

Conclusion and Perspective

Evolutionarily, there is a high basal drive for seeking and eating food, which makes sense in an environment where food is scarce. In our modern society, however, where high-energy food is abundant and lifestyles are more sedentary, this drive may contribute to the obesity epidemic seen worldwide. Globally, 400 million people were considered to be obese in 2006, based on their BMI. Obesity has severe health implications and treating these is very expensive. Therefore, there is great interest in exploring the appetite-regulating system and developing potential therapeutic agents to decrease food intake and body weight. Although much is still to be learned about the gut–brain communication, we now know that gut hormones are fundamental in physiological body-weight regulation. Great efforts are therefore being applied to fully understanding the interacting mechanisms relaying information from the gut to the brain. Limited or short-lasting decrease in food intake and body weight has been seen with many gut hormones or related agonist and antagonist compounds. The effects have been improved by chemically increasing the bioavailability of the compounds. However, more recent studies show greater effect by combining the effects of several hormones, a strategy that is already being applied and appears to be promising for the development of effective gut-hormone-derived weight-reducing therapeutics.

Glossary

Activation energy The minimum amount of energy required (for water molecules to come across aquaporin channels).

Hydropathy analysis A technique which uses a scale (containing some sort of free energy-derived value for each amino acid) windowing to determine the hydrophobic nature of a protein sequence.

Immunogold electron microscopy A form of electron microscopy in which gold particles are used to label

antibodies so that the protein of interest can be localized by localizing gold particles.

Loss-of-function mutations The change in the DNA sequence of a gene with gene product having less or no function.

Phosphorylation The addition of a phosphate group (PO_4^{3-}) to an amino acid of a protein.

Water homeostasis A state of water equilibrium.

Introduction

Every living organism is primarily water, and approximately 70% of the human body mass is also water. Thus, the distribution and movement of water through tissues are fundamental to life. The surface of our brains is protected by cerebrospinal fluid. The orbits of our eyes are filled with aqueous humor, and the exterior surface by a thin film of tears. We sweat during exercise to maintain normal body temperature. Every day our kidneys absorb 99% of water from the glomerular filtrate, concentrating urine, and thereby protecting us from dehydration.

Water can pass across biological membranes (lipid bilayers) by simple diffusion relatively slowly. However, over the past several decades, multiple research groups have reported that membranes of certain tissues have very rapid water permeability, such as mammalian red cells and amphibian bladder. No pharmacologic inhibitors of diffusion are known. However, an important experiment in 1970 established that water transport into red cells is inhibited by mercurials and restored by chemical reducing reagents. These observations indicated that water-specific channels must be proteins with free sulfhydryls and characteristically low Arrhenius activation energy (Figure 1).

Discovery of Aquaporin-1

Although sought by multiple groups of investigators, water-transporting molecules remained elusive for decades, and most scientists were dubious that they even existed. Interest in water channels dramatically rose after the publication of the functional description of a protein now known as aquaporin-1 (AQP1). By using *Xenopus laevis* oocytes to express AQP1, dramatic explosions were viewed microscopically after transferring oocytes to hypotonic solutions (Figure 2), the first demonstration of molecular water channels.

AQP1-mediated water permeability is distinct from simple diffusion. First, water movement through AQP1 has higher capacity and lower activation energy ($E_a < 5 \text{ kcal mol}^{-1}$) than diffusion

($E_a > 10 \text{ kcal mol}^{-1}$). Second, water but not protons (H_3O^+) pass through the AQP1 channel pore. Subsequent experiments revealed that water transport by AQP1 is inhibited by mercurials, is restored by reducing agents, such as β -mercaptoethanol, and lacks measurable membrane currents – all features consistent with the previous predictions of water channels.

Following discovery of AQP1, multiple research groups joined the quest and isolated homologous proteins from plant, animal, and microbial tissues with high water transport, and the field grew rapidly.

Structure of AQP1

Hydropathy analysis of the deduced AQP1 protein sequence revealed a novel topology—two tandem repeats, each formed by three transmembrane domains, oriented at 180° with respect to each other in the lipid bilayer. In this unique symmetry, loops B and E each carries a signature asparagine–proline–alanine (NPA) motif highly conserved within the AQP family (Figure 3, upper panel). Cysteine 189 (Cys-189), proximal to the second NPA motif, is the mercurial inhibition site. By mutagenesis it was established that six bilayer-spanning domains surround a central pore containing loop B, dipping into the bilayer from the cytoplasmic surface, and loop E, dipping into the bilayer from the extracellular surface (Figure 3, lower panel). Resembling the ancient timepiece, this model was termed as the ‘hourglass’ and was later confirmed by high-resolution structural analysis.

Efforts were directed to solving the AQP1 structure because of its fundamental role in physiology. Structures of functional human AQP1 were first achieved using electron crystallography by the Engel and Fujiyoshi groups at $3.8\text{-}\text{\AA}$ resolution. The structures of *Escherichia coli* glycerol facilitator (GlpF) and bovine AQP1 were subsequently determined at $2.2\text{-}\text{\AA}$ resolution by X-ray crystallography. Although present as a tetramer in the cell membrane, each AQP1 monomer contains its own pore and works independently. This organization is distinct from most ion channels, where four subunits surround a central pore. Four residues, Phe-56, His-180, Cys-189 (the

Figure 2 Functional expression of AQP1 water channel in *X. laevis* oocytes. (Left panel) A control oocyte (left) and an AQP1-expressing oocyte (right) in isotonic solution. (Right panel) The AQP1-expressing oocyte explodes after transferred to hypotonic buffer. The control oocyte has swollen negligibly, whereas the AQP1-expressing oocyte has exploded due to the fast water influx along the osmolality gradient. mercury sensitive residue), and Arg-195, form the 2.8-Å constriction of the pore. The narrowest part of GlpF is about 1 Å wider than AQP1, providing sufficient space for the larger glycerol molecule to pass through.

These structures also shed light upon the mechanism of proton (H_3O^+) exclusion. In solution, both H_2O and H_3O^+ exist. Water molecules linked to each other by hydrogen bonds allow protons to jump rapidly along a column of water, referred to as a 'proton wire'. Arg-195, the highly conserved residue in the aquaporin family, provides a positive charge at the narrowest pore area of the channel. His-180 becomes protonated at lower pH and provides a second positive charge. These two residues, together with the two asparagines residues in NPA motifs (Asn-76 and Asn-192 in human AQP1), effectively prevent proton passage by electrostatic repulsion and water dipole reorientation (Figure 4). The structure of AQP1 is ideally suited to its biological functions. This mechanism allows human kidneys to reabsorb water while excreting acid – necessary to maintain hydration while preventing systemic acidosis. Moreover, the membrane potential in plants is derived from the pH gradient that exists in spite of rapid transmembrane water movements.

Physiological Functions of AQP1

Approximately 180 l of plasma are filtered by our kidneys every day to eliminate toxic wastes and maintain the appropriate blood pH and ionic composition. By light microscopy and immunoelectron microscopy, AQP1 was visualized in renal proximal convoluted tubules and descending thin limbs of the loop of Henle, segments with constitutively high water permeability. In contrast, the ascending segments are permeable to ions but not water and lack AQP1 proteins. Furthermore, AQP1 protein is present only in the apical and basolateral plasma membranes of these tissues and not in intracellular membranes. These studies provide clear evidence for the physiological and pathological roles of AQP1 – constitutively transporting large amounts of water from tubular lumen to the interstitium and then into the vascular space with the driving force provided by small, standing osmotic gradients created by solute transporters (Figure 5). AQP1 was also found in other tissues with important secretory roles such as nonpigmented epithelium in anterior compartment of eye (aqueous humor), cholangiocytes (bile), and capillary endothelium in many organs including bronchial circulation of lung.

Human AQP1 gene was mapped on the short arm of chromosome 7 by fluorescence *in situ* hybridization where it coincides with the Colton blood group antigens. The Colton A and Colton B antigens correspond to a polymorphism (alanine–valine) in an extracellular domain of AQP1 protein. Colton-null is extremely rare, with only six kindreds documented by the International Blood Group Reference Laboratory. The Colton-null individuals were found to be homozygous for knockout mutations in the AQP1 gene, and their red-cell membranes lacked AQP1 protein and exhibited marked reductions in red-cell osmotic water permeability.

In a clinical renal function study, two unrelated AQP1-null individuals showed no obvious defects under baseline conditions; however, both exhibited markedly reduced renal concentration after overnight thirsting ($450 \text{ mosmol kg}^{-1}$ in AQP1-null individuals vs. $1000 \text{ mosmol kg}^{-1}$ in normals). Although they are extremely rare, individuals with defects in AQP1 would be at risk for life-threatening clinical problems when they are dehydrated due to environmental causes or other illnesses.

Figure 5 Constitutive transcellular water movements by AQP1 through a single cell in renal proximal tubule epithelium. Reproduced from Nielsen S, Smith BL, Christensen EI, Knepper MA, and Agre P (1993) CHIP28 water channels are localized in constitutively water-permeable segments of the nephron. *Journal of Cell Biology* 120: 371–383, with permission.

In a follow-up study of AQP1 functions in vascular endothelium, high-resolution computed tomography was applied to scan the lungs before and after saline infusion. Normal individuals had a significant increase in the airway wall thickness with early peribronchiolar edema and moderate pulmonary congestion. Interestingly, none of the AQP1-null individuals had increased bronchiolar wall thickness. This study showed that AQP1-null individuals have significant reduction in vascular water permeability, indicating the critical role of AQP1 in lung. While yet unproven, such AQP1-null individuals may be at risk of pulmonary dysfunction due to reduced absorption of amniotic fluid at birth.

AQP2 – Vasopressin-Regulated Water Channel in Renal Collecting Ducts

Water transport occurring in renal collecting ducts (CDs) is regulated by the antidiuretic hormone arginine vasopressin (AVP). The lack of AQP1 in CDs predicted the existence of another aquaporin family member, AQP2, which is predominantly expressed in CD principal cells. In the absence of AVP, AQP2 is largely restricted to intracellular vesicles, and dilute urine is released (the diuretic state). In the presence of AVP, AQP2 is redistributed to the apical membrane, accompanied by increased water permeability in CDs with corresponding release of concentrated urine (the antidiuretic state). After vasopressin is removed, AQP2 is re-internalized and the CD water permeability returns to baseline. Humans go from the diuretic state to the antidiuretic state and back to the diuretic state as water intake changes.

Figure 6 Vasopressin-regulated AQP2 translocation and transcellular water movements. Reproduced from Nielsen S and Agre P (1995) The aquaporin family of water channels in kidney. *Kidney International* 48: 1057–1068, with permission.

Subsequently, researchers found that AQP2 is regulated by exocytosis. Briefly, AVP binds to vasopressin 2 (V2) receptor at the basolateral membrane of CD principal cells, activating a cyclic adenosine monophosphate (cAMP)-dependent phosphorylation cascade. The phosphorylation at Ser-256 and probably other residues in AQP2 results in movement to the apical plasma membrane by exocytosis. AQP3 and AQP4 were later shown to reside on the basolateral membranes of CD principal cells. Thus, water from the primary urine enters the apical membrane of principal cells through AQP2 and exits from the basolateral membranes through AQP3 or 4, following the transcellular pathway (Figure 6). Certain genetic mutations in AQP2 have been reported to cause nephrogenic diabetes insipidus, where the kidney fails to concentrate urine in response to vasopressin and patients show severe clinical symptoms. Even milder forms of renal defective urine concentration, such as bedwetting by small children, are believed to represent temporary deficiencies of AQP2 that occur during growth.

Other Aquaporin Family Members

Aquaporin proteins have been identified in many diverse forms of life. At present, 13 homologs (AQP0–AQP12) have been identified in mammals, with a wide tissue and organ distribution and transport specificities (summarized in Table 1). The physiological roles of AQP0–AQP9 are relatively well elucidated; however, little is known about the functions of AQP10, AQP11, and AQP12. According to protein sequences and substrate specificity, most mammalian aquaporins can be classified into two subgroups, classical aquaporins (water-

Table 1 The predominant distribution and permeability of mammalian aquaporins

	Predominant distribution	Permeability and other roles
AQP0	Lens	Water (low), cell adhesion
AQP1	Red cells, kidney, lung, vascular endothelium, brain, eye	Water (high)
AQP2	Kidney, vas deferens	Water (high), regulated by exocytosis
AQP3	Kidney, skin, lung, eye, colon	Water (high), glycerol (high), urea (moderate)
AQP4	Brain, muscle, kidney, lung, stomach, small intestine	Water (high)
AQP5	Salivary gland, lacrimal gland, sweat gland, lung, cornea	Water (high)
AQP6	Kidney	Water (low), anions
AQP7	Adipose tissue, kidney, testis	Water (high), glycerol (high), urea (high), arsenite
AQP8	Testis, kidney, liver, pancreas, small intestine, colon	Water (high)
AQP9	Liver, leukocytes, brain, testis	Water (low), glycerol (high), urea (high), arsenite
AQP10	Small intestine	Water (low)
AQP11	Brain, testis, liver, kidney, heart	Unknown
AQP12	Pancreas	Unknown

Reproduced from King L, Kozono D, and Agre P (2004) From structure to disease: The evolving tale of aquaporin biology. *Nature Reviews. Molecular Cell Biology* 5(9): 687–698 (review), with permission.

specific) and aquaglyceroporins (permeable to glycerol or other small, uncharged solutes).

It should be emphasized that the functional roles of sequence-related proteins may be more complex. As discussed below, AQP0 may have a second role as a cell adhesion molecule, and AQP6 is an anion-selective channel. The evolutionary relationships of human AQP1–10 are shown in Figure 7. Lacking the signature motif, NPA (pore-lining NPA), as well as certain highly conserved residues, AQP11 and AQP12 appear to be more distantly related to the other homologs.

AQP0, initially called major intrinsic protein (MIP), is expressed only in fiber cells of lens. In an AQP0 structure revealed by electron microscopy of two-dimensional (2D) crystals, every subunit of a tetramer in one lipid layer interacts with two subunits of a tetramer in the adjacent layer. As a result, the pore is too narrow for water passage. This conformation explains why AQP0 has fairly low water permeability, and also demonstrates its structural role in cell–cell adhesion. Two structurally significant AQP0 amino acid substitutions were identified in two kindreds with congenital cataracts of dominant inheritance, suggesting that AQP0 is a risk factor for cataract development.

AQP4 is expressed in multiple organs, including brain. By immunogold electron microscopy, AQP4 has been shown to be highly concentrated in astroglial endfeet membranes, forming microcrystalline lattices referred to as ‘square arrays’. A C-terminal PDZ-binding (PDZ, postsynaptic density protein –

Figure 7 The evolutionary relationships of human aquaporins and aquaglyceroporins with two *E. coli* proteins, AqpZ and GlpF. Reproduced from Agre P, Bonhivers M, and Borgnia M (1998) The aquaporins, blueprints for cellular plumbing systems. *Journal of Biological Chemistry* 273: 14659–14662, with permission.

Drosophila disk large tumor suppressor – zonula occludens-1 protein) motif stabilizes the perivascular localization of AQP4 in brain through binding to a structural protein complex. Results from AQP4 localization and biological function studies, together with analysis of AQP4-null mice, suggest that AQP4 may permit water to cross the blood–brain barrier that separates parenchyma and vascular space. The importance of AQP4 in human cerebral edema is expected.

AQP5 resides in secretory glands that facilitate the release of large amounts of body fluids, including saliva, tears, and airway surface liquid. AQP5-null mice have diminished ability to salivate and sweat. In a subset of humans with Sjögren’s syndrome, apparent mislocalization of AQP5 coincides with dry eyes and dry mouth, clinical hallmarks of the disorder. Failure of AQP5 to traffic to the apical surface membranes of the glandular epithelium may contribute to decreased lacrimation in these patients.

Although similar to AQP2 in terms of protein sequence, AQP6 has unique subcellular distribution and distinct biophysical functions. AQP6 is localized on intracellular vesicles in renal alpha intercalated cells and apparently transports anions, particularly nitrate, when activated by low pH. Mutagenesis studies suggest that an asparagine residue, Asn-60, at the contact point between the second and fifth transmembrane domains in AQP6 may function as a teeterboard which is needed for rapid structural oscillations during anion permeation. While still unproven, AQP6 may play a role in acid–base equilibrium.

The aquaglyceroporins, AQP3, AQP7, and AQP9, are permeated by water and other small solutes such as glycerol and urea.

AQP3 may contribute to skin integrity, and this protein is heavily expressed in basal layer of skin epithelium. Evidence indicates that expression of AQP3 is increased during wound healing and decreased during aging of sun-exposed skin. Important roles are being established for AQP7 in adipocytes and AQP9 in liver. During fasting, triglycerides in adipocytes are degraded into glycerol and fatty acids. Glycerol released from fat cells through AQP7 on plasma membrane enters hepatocytes through AQP9 on plasma membrane. Working together, AQP7 and AQP9 form an axis for energy transfer and maintenance of normal blood glucose levels even during starvation.

Surprisingly, AQP7 and AQP9 were also found to be permeated by heavy metals, including arsenite, providing a possible route for excretion of the extremely toxic arsenicals. Considering its expression in leukocytes, AQP9 could be a pharmacological pathway for the selective toxicity of arsenite which is used as an agent to treat promyelocytic leukemia.

Unlike human red cells, which express AQP3, the major glycerol channel in mouse red cells is AQP9, and AQP9-null mice infected with malaria parasite *Plasmodium berghei* are slightly protected during the initial phase of infection compared with wild-type mice. These results suggest that the AQP9-mediated transport pathway may contribute to the virulence of intra-erythrocytic stages of malarial infection.

An aquaglyceroporin homolog, PbAQP, exists in rodent malaria parasite *Plasmodium berghei*. The parasite has to utilize host glycerol for its own lipid biosynthesis and membrane biogenesis. Furthermore, the parasite also faces rapid and significant volume change in host red blood cells. As the only channel for water and glycerol passage, PbAQP contributes to the parasite's high proliferation rate and the ability to evade physiological stresses. Targeted disruption of PbAQP has shown that mice infected with PbAQP-null parasites survived longer than those infected by wild-type parasites, suggesting that PbAQP plays an important role in the blood-stage development of the parasite.

Functions of AQP10, 11, and 12 are not well understood. Human AQP10 may be a pseudogene and the number of paralogs is being debated. Analysis of mice with targeted disruption of *Aqp10* and *Aqp12* has not revealed their physiological functions. Interestingly, the AQP11-null mouse has been reported to sustain fatal polycystic kidneys, while the pathophysiological mechanism is not clear yet.

Unlike animals, plants cannot effectively evade unfavorable climatic conditions. Therefore, a fine-tuned adaptation mechanism including water balance is fundamental for plant physiology. Plants contain a large number of aquaporins (38 in *Arabidopsis*), with a variety of functions in root water uptake, reproduction, or photosynthesis. Plant aquaporins conduct water, and some may also conduct NH_3 , CO_2 , and H_2O_2 . Some plant aquaporins, including the spinach protein SoPIP2;1, have been reported to exhibit gating in response to changes in pH and phosphorylation.

Methanothermobacter marburgensis, a methanogenic archaeon thriving in anaerobic environments even at 65 °C, also carries an aquaporin, aquaporin-M (AQPM), which has been proposed to facilitate transport of hydrogen sulfide *in vivo*. Its existence demonstrates the ubiquity of aquaporins in nature and the crucial importance of this family.

Several fungal aquaporins have also been studied. *Saccharomyces cerevisiae* expresses two, AQY1 and AQY2, and

Candida albicans expresses one, AQY1. Yeast aquaporins from wild-type organisms all facilitate water transport when expressed in oocytes, whereas sequences obtained from laboratory strains carry loss-of-function mutations. Functional AQY2 protein from *Saccharomyces chevalieri* was expressed in *aqy1* and *aqy2* double-null yeast and this caused a reduction in cell surface hydrophobicity, suggesting that fungal aquaporins may promote metabolic advantages or affect virulence by enhancing cell dispersion.

Eight aquaporin genes (*aqp1–8*) are present in the genome of the important flatworm *Caenorhabditis elegans* genome. These aquaporins are expressed at multiple sites (such as intestine, excretory cells, and hypodermis) that play important roles in osmoregulation. Some members have water and glycerol transport activities when measured in *Xenopus* oocytes. However, worms with targeted disruption in one or more aquaporin genes did not show obvious functional clues to their roles, so the specific physiological roles of aquaporins in *C. elegans* await further analysis.

Insects have also been reported to contain members of the aquaporin family – usually at the sites where fluid transport is high, such as digestive tract of sap-sucking *Cicadella viridis*, silk glands of silkworms, and salivary glands of blood-feeding dog ticks. Moreover, the *Drosophila* neurogenic protein, big brain (Bib), has sequence similarity to aquaporins and has been described to exhibit novel cellular functions in endosome maturation and notch receptor trafficking.

Summary

Water is the major component of all living organisms, and water homeostasis is crucial to life, especially at times of environmental or physiological stress. The 2003 severe heat wave in Europe lasted 2 weeks. Public health officials reported tens of thousands of deaths from severe dehydration and related clinical complications. In many instances, it is likely that the victims were unable to adequately compensate by renal concentration and sweat mechanisms. Thus, aquaporin physiological pathways may have been overwhelmed. Since the discovery of AQP1 water channel, this field has expanded dramatically. Researchers from several countries are now studying aquaporins in multiple types of organisms. Besides water, glycerol, and urea permeation, additional roles for aquaporins have been proposed as structural membrane support, heavy metal transport, and even gas transport. Although many questions remain unanswered, knowledge obtained from studies of aquaporins provides improved understanding of the pathophysiology of water homeostasis and may in the future provide clinical benefits in treating a wide range of diseases.

Arachidonic Acid Regulated Calcium Channel

T J Shuttleworth, University of Rochester Medical Center, Rochester, NY, USA

Glossary

AKAP (A-kinase anchoring protein) A family of proteins that binds to the regulatory subunits of the cyclic AMP-activated kinase protein kinase A, to provide a scaffold enabling the targeting of various other proteins (e.g., kinases, phosphodiesterases, phosphatases, etc.) in close proximity to PKA, whose activity they regulate.

ARC channel (arachidonic acid regulated Ca^{2+} channel) A small conductance, highly Ca^{2+} -selective channel that is specifically activated by low concentrations (2–8 μM) of arachidonic acid in a manner that is entirely independent of any store depletion (cf. CRAC channels).

CRAC channel (Ca^{2+} release-activated Ca^{2+} channel) Another small conductance, highly Ca^{2+} -selective channel that is specifically activated following depletion of intracellular Ca^{2+} stores.

Orai A group of three recently identified novel proteins (Orai1–3) that are the pore-forming components of both CRAC and ARC channels.

STIM1 (stromal interacting molecule 1) A protein that was originally identified as a cell-surface protein that played a key role in interactions between hematopoietic cells and cells in the bone marrow stroma, and as a growth suppressor of certain tumors. More recently, it was identified as playing an essential role in the activation of store-operated Ca^{2+} entry via its ability to sense falling Ca^{2+} concentrations within the intracellular stores and to subsequently activate the plasma-membrane store-operated Ca^{2+} channels. Subsequent studies have revealed that the pool of STIM1 that constitutively resides in the plasma membrane plays an equally critical role in the activation of the store-independent ARC channels.

TRPC channels (canonical TRP channels) A subgroup of the mammalian transient receptor potential (TRP) channels that is most closely related to the TRP channels of *Drosophila*. They are essentially nonselective cation channels that are activated under various conditions of receptor activation, some of which are claimed to be store-operated and to involve STIM1, although this remains controversial.

Different Modes of Ca^{2+} Entry and the Discovery of the ARC Channels

The receptor-activated entry of Ca^{2+} in nonexcitable cells plays a key role in the generation and modulation of the resulting intracellular Ca^{2+} signals that are known to be responsible for a wide variety of critical cellular responses, including cell growth and proliferation, differentiation, movement, secretion, metabolism, and cell death. Our understanding of the underlying mechanisms and pathways involved in such entry began with the work of Putney in the mid-1980s and his development of the concept of capacitative, or store-operated, Ca^{2+} entry, where activation of the entry of Ca^{2+} is strictly a consequence of the depletion of intracellular Ca^{2+} stores. Demonstration of the presence of such store-operated entry pathways in almost all cell types examined has led to the widely held belief that this specific mode of Ca^{2+} entry represents the major, if not the only, mode of such receptor-activated entry in nonexcitable cells. However, examination of the literature reveals that direct evidence demonstrating a principal role for such pathways in the various receptor-activated Ca^{2+} signals and responses seen in these different cell types is limited. More specifically, although various conductances have been proposed to provide the route for store-operated Ca^{2+} entry in different cells types, the most thoroughly characterized store-operated Ca^{2+} channel remains the Ca^{2+} -release activated Ca^{2+} (CRAC) channel. This conductance was originally identified in T lymphocytes and in mast cells, and here it is clear that the activity of the CRAC channels is critical for the physiological activation of these cells. However, examination of the properties of this channel and its activation

raises several questions as to its ability to function as the exclusive pathway of agonist-activated Ca^{2+} entry in other cell types. These include a requirement for a rather profound depletion of intracellular stores before any activation begins, the subsequent relatively slow rate of activation, and evidence indicating that such activation occurs in an essentially all-or-none fashion. Together, these features are difficult to reconcile with the predicted requirement of a finely regulated, graded Ca^{2+} response in order to accurately coordinate the appropriate cellular response to any particular increase in the Ca^{2+} signal. On a more general level, it should also be remembered that depletion of the intracellular Ca^{2+} stores can be induced by a variety of different events, many of which are unrelated to the normal, physiologically relevant, agonist-activated signaling pathways. For example, store depletion can result from an inhibition of the sarcoplasmic and endoplasmic calcium (SERCA) pump such as may occur during ischemia, or an increase in passive leak pathways such as those provided by the presenilins, as well as exposure to oxidants and other cellular stressors. Finally, the absolute requirement for a sustained depletion of intracellular Ca^{2+} stores in order to activate these conductances is potentially problematic, as such depletion can seriously impact various vital cell processes, the most obvious being the correct folding and processing of secretory and membrane proteins. Together, consideration of these issues suggests that, although store-operated modes of Ca^{2+} entry can be demonstrated in almost all cell types, their principal role might lie in some process other than normal signaling in response to agonist stimulation. Indeed, given their exclusive dependence on the depletion of intracellular Ca^{2+} stores for activation, the most

likely primary role for such store-operated entry pathways would seem to be the maintenance of adequate levels of Ca^{2+} in the ER.

These arguments eventually led to the search for possible alternate pathways of agonist-activated Ca^{2+} entry whose activity might be more directly or specifically connected to agonist-induced receptor activation. The result of one such search was the discovery of an entry pathway whose activation is entirely unaffected by store depletion and is instead dependent on the agonist-activated, receptor-mediated generation of arachidonic acid. Initial evidence in support of such a pathway included the demonstration that addition of low concentrations ($<8 \mu\text{M}$) of exogenous arachidonic acid resulted in an entry of Ca^{2+} without detectable release from stores, that the generation of arachidonic acid was increased following addition of low physiologically relevant concentrations of agonists to cells, and that the pharmacological inhibition of such agonist-activated arachidonic acid generation resulted in the inhibition of the associated entry of Ca^{2+} . Finally, it was shown that the activation of the entry of Ca^{2+} was an effect of arachidonic acid itself, and not any of its metabolites. Subsequently, much as the CRAC channel was eventually identified as the archetypal store-operated Ca^{2+} -selective conductance, the specific conductance responsible for this store-independent, arachidonic acid-activated Ca^{2+} entry was identified and named the arachidonic acid regulated Ca^{2+} (ARC) channel. In the approximately 10 years since their first identification, considerable details of these channels have been revealed, including their biophysical and pharmacological profiles, specificity for arachidonic acid, occurrence in different cell types, and, most recently, the molecular basis of their composition and regulation. Moreover, there are now clear examples of situations where these ARC channels have been shown to play unique, critical roles in the physiological responses of various cell types.

Characteristics of ARC Channels

Much like the CRAC channels, ARC channels represent a relatively small (with typical whole-cell currents of approximately $0.5\text{--}1.5 \text{ pA pF}^{-1}$ in most cell types), highly Ca^{2+} -selective conductances. Consistent with this high selectivity for Ca^{2+} , their current-voltage relationship reveals marked inward rectification and a reversal potential in excess of $+60 \text{ mV}$ (Figure 1). Similarly, like most Ca^{2+} channels, they are blocked by La^{3+} and by Gd^{3+} with complete inhibition achieved by $50\text{--}100 \mu\text{M}$ and $5 \mu\text{M}$, respectively. However, unlike the CRAC channels, they are not affected by moderate acidification of the external medium, and they are unaffected by the widely used, but relatively nonspecific, drug 2-aminoethoxydiphenyl borate (2-APB). In addition, the ARC channels do not share the clear fast inactivation during brief pulses to negative potentials that are a characteristic of CRAC channels (Figure 1).

Activation of the ARC channels occurs at the same low concentrations of exogenous arachidonic acid ($2\text{--}8 \mu\text{M}$) as was seen to induce store-independent Ca^{2+} entry in the earlier studies (see above). Importantly, such concentrations are clearly physiologically relevant as they are similar to values for the K_d 's of the cytosolic enzymes that metabolize arachidonic acid. Moreover, effective and specific activation of the conductance by these low concentrations is a critical property

Figure 1 Basic features of currents through endogenous ARC channels. (a) Whole-cell patch-clamp recording of inward current density at -80 mV in a HEK293 cell. Free Ca^{2+} concentration in the external (bath) solution was 10 mM Ca^{2+} and in the internal (pipette) solution was 100 nM . At the point indicated (arrow), $8 \mu\text{M}$ arachidonic acid was added to the external bath. (b) Representative current-voltage relationship of the arachidonic acid-activated current showing the marked inward rectification and very positive reversal potential typical of a highly Ca^{2+} -selective conductance. (c) Comparison of the current traces through the ARC channels (left) and through the corresponding store-operated CRAC channels (right) present in the same cells during brief (250 ms) pulses to -120 mV . Note that the fast-inactivation characteristic of currents through CRAC channels is absent in the ARC channel currents.

as it is known that arachidonic acid at higher concentrations (e.g., $>10\text{--}20 \mu\text{M}$) can induce significant effects on the integrity of the cell membrane, resulting in the permeation of even relatively large, normally impermeant, ions such as NMDG^+ . Activation of the ARC channels also shows a high specificity for arachidonic acid, as both saturated fatty acids (e.g., palmitic acid) and mono-unsaturated fatty acids (e.g., oleic acid) are completely without effect. Even among other polyunsaturated fatty acids, only linoleic acid shows a small effect and this probably arises from the fact that this fatty acid is a metabolic precursor for arachidonic acid. In addition, and in contrast to certain members of the transient receptor potential channel (TRPC) family of channels, the ARC channels are entirely unaffected by diacylglycerol and its analogs. Finally, experiments using the nonpermeable arachidonic acid analog arachidonyl-coenzyme

A demonstrated that the activation of the channel by arachidonic acid is exclusively via an action of the fatty acid at the inner face of the membrane.

Since their initial discovery and characterization almost 10 years ago, ARC channels (or, at least, conductances displaying all the key features of these channels) have been described in a wide variety of different cell types, including many common cell lines (HEK293, HeLa, COS, and RBL), SY6Y neuroblastoma cells, K562 erythroleukemia cells, as well as the exocrine parotid and pancreatic acinar cells, and the endocrine pancreatic β cells. In many of these cell types, the ARC channels coexist with store-operated channels, including the biophysically very similar CRAC channels. Nevertheless, it can be demonstrated that these two coexisting channels represent entirely distinct entities. Thus, using the whole-cell patch clamp mode in HEK293 cells, it has been shown that maximal activation of the CRAC channels by store depletion has no effect on the magnitude of the subsequently activated ARC channel currents induced by addition of exogenous arachidonic acid – in other words, at least under whole-cell patch clamp conditions, the two currents are strictly additive in the same individual cell.

Reciprocal Regulation of ARC Channels and CRAC Channels

As described above, under whole-cell patch clamp conditions, currents through the ARC channels and coexisting store-operated CRAC channels are strictly additive. However, it is important to note that such additivity of the two currents does not appear to occur in the intact cell. The reason for this difference is that, in the whole-cell patch clamp configuration, the presence of buffers in the pipette solution clamps the intracellular Ca^{2+} concentration at resting levels while, in the normal intact cell situation, activation of store-operated Ca^{2+} entry typically results in a sustained elevation of intracellular Ca^{2+} . Studies have shown that this sustained elevation in intracellular Ca^{2+} results in the activation of the Ca^{2+} -calmodulin-dependent phosphatase calcineurin and this, in turn, induces an inhibition of ARC channel activity. Consequently, in the intact cell, activation of the store-operated channels (e.g., CRAC channels) will result in an inhibition of the ARC channels, a process that has been described as the 'reciprocal regulation of Ca^{2+} entry'.

The discovery that the phosphatase calcineurin inhibits the ARC channels suggested that the activity of these channels must be dependent, in some way, on phosphorylation. Subsequent studies showed that the specific kinase responsible was the cyclic AMP-dependent protein kinase A (PKA). Thus, the currents through the ARC channels measured in HEK293 cells maintained under normal culture conditions following addition of low concentrations of arachidonic acid are inhibited by preincubation with the cell-permeable PKA-specific inhibitory peptide myristoylated PKI but are unaffected by inhibition of either protein kinase C (with calphostin) or protein kinase G (with KT5823). Correspondingly, the addition of forskolin, particularly after induction of the calcineurin-mediated dephosphorylation, resulted in enhanced arachidonic acid-activated ARC channel currents. In addition, it has been shown that this action of PKA in modulating ARC channel activity involves a member of the A-kinase anchoring protein (AKAP) family. For example,

studies utilizing a cell-permeable stearylated version of a synthetic peptide that disrupts the binding of PKA to AKAPs (st-Ht31 peptide) both inhibited normal ARC channel currents and blocked the above effects of forskolin on the currents.

Molecular Nature (and Activation) of ARC Channels

Although the CRAC channel had been originally described and characterized in the early 1990s, the molecular nature of its structure and regulation were unknown until the recent identification of stromal interacting molecule 1 (STIM1) as the sensor of store depletion, and the discovery of Orai1 as the molecule that forms the CRAC channel itself. These studies revealed that STIM1 located in the membrane of the endoplasmic reticulum (ER) sensed the depletion of Ca^{2+} in these stores via a luminal Ca^{2+} -binding EF-hand motif present in the N-terminal region of the protein. Loss of Ca^{2+} from this motif results in the oligomerization of STIM1 and its translocation to regions of the ER that lie adjacent to the plasma membrane. Here, it interacts with Orai1 resulting in the activation of the CRAC channels.

Given this clearly demonstrated role of STIM1 as the ER Ca^{2+} sensor in the activation of the CRAC channels, it would be expected that STIM1 would be unlikely to play any role in the activation of the store-independent ARC channels. However, experiments showed that ARC channel currents were increased by overexpression of STIM1 and reduced by siRNA knock-down of the endogenous protein, in a manner that was indistinguishable from that seen with the CRAC channels present in the same cells. Reconciliation of these unexpected results began with the realization that the STIM1 protein is not exclusively restricted to the ER membrane. In fact, it was originally identified as a cell surface (i.e., plasma-membrane) protein present in the stromal cells of the bone marrow, where it was involved in interactions between these cells and hematopoietic cells (specifically pre-B lymphoid cells). Studies have shown that the pool of STIM1 that is resident in the plasma membrane is relatively small (approximately 10–25% depending on cell type), and its delivery to this location is strictly dependent on N-linked glycosylation at two sites within the N-terminal region of the protein (Asn131 and Asn171). To examine the effect of specifically eliminating this cell-surface pool of STIM1, cells treated with an siRNA targeting the endogenous STIM1 were transfected with an siRNA-resistant STIM1 construct in which these two glycosylation sites were mutated (N131Q and N171Q) – thereby effectively replacing the native STIM1 with the mutant version. Examination of both ARC and CRAC currents in these cells revealed that while CRAC channel currents were unaffected, the ARC channel currents in the same cells were profoundly inhibited (Figure 2). These data clearly established that it is the pool of STIM1 resident in the plasma membrane that is essential for activation of the ARC channels. As yet, exactly how the plasma membrane STIM1 acts to regulate the activation of the ARC channels is unknown. However, it is important to note that, in the case of this plasma membrane pool of STIM1, the Ca^{2+} -binding N-terminal EF-hand motif will lie in the extracellular environment. Given the high and relatively stable Ca^{2+} concentrations of this environment, it is clear that the EF-hand of this pool of STIM1 would always, under normal circumstances, be in the Ca^{2+} -bound state.

Figure 2 Expression of STIM1 in which the glycosylation sites that are essential for delivery of the protein to the plasma membrane are mutated reveals that activation of ARC channels is exclusively dependent on the pool of STIM1 that constitutively resides in the plasma membrane. (a) Western blot of STIM1 in HEK293 cells, showing the levels of total STIM1 in untransfected cells (cont), in cells transfected with an STIM1 siRNA construct (K/D), and in siRNA-treated cells following transfection with an siRNA-resistant STIM1 in which the two N-glycosylation sites have been mutated (N131Q and N171Q) (K/D + mut). (b) The effects of expressing siRNA-resistant versions of either wild-type STIM1 (gray bars) or the glycosylation-mutant STIM1 (black bars) in STIM1 siRNA-treated cells. Currents through the store-operated CRAC currents (left panel) are unaffected by the expression of the glycosylation-mutant STIM1, while similar expression of the glycosylation-mutant STIM1 results in a profound inhibition of ARC channel currents (right panel). Reproduced from Mignen O, Thompson JL, and Shuttleworth TJ (2007) STIM1 regulates Ca^{2+} entry via arachidonate-regulated Ca^{2+} -selective (ARC) channels without store-depletion or translocation to the plasma membrane. *Journal of Physiology* 579: 703–715.

This stands in marked contrast to the critical role of the loss of Ca^{2+} from the luminal EF-hand of STIM1 in the ER in the regulation of the store-operated CRAC channels. Consequently, whatever the mechanism by which STIM1 regulates the ARC channels, it must be very different from the way it activates the CRAC channels.

The demonstration that STIM1 is required for the activation of both CRAC and ARC channels, although entirely distinct pools of this protein are responsible, and that both channels display very similar biophysical properties raised the possibility that, as had already been demonstrated for the CRAC channels, Orai proteins may form the ARC channel. Three distinct, but closely related Orai proteins (Orai1–3) are expressed in mammals, and while the CRAC channel is formed exclusively from Orai1, studies have demonstrated that both Orai1 and

Orai3 are required for the formation of the functional ARC channel. Thus, overexpression of Orai1 in cells stably expressing STIM1 results, not only in markedly increased CRAC channel currents but also in similar increases in ARC channel currents. Correspondingly, expression of the dominant-negative (E106Q) Orai1 mutant effectively eliminates both CRAC and ARC channel currents. However, expression of the corresponding dominant-negative E81Q Orai3 mutant essentially eliminates currents through the ARC channels and has no effect on the CRAC channel currents in the same cells.

ARC Channel Structure

Recent studies, utilizing a variety of different approaches, have demonstrated that the functional CRAC channel is a tetrameric assembly of Orai1 subunits. Given this, and the above data demonstrating the essential requirement for both Orai1 and Orai3 subunits in the functional ARC channel, the most likely structure for the channel would seem to be some form of heterotetrameric assembly of Orai1 and Orai3 subunits. However, examination of the conductances resulting from each of the possible tetrameric combinations of Orai1 and Orai3 subunits expressed in the form of pre-assembled concatenated constructs revealed unexpected results. Thus, while expression of some of these constructs resulted in significant arachidonic acid-activated, highly Ca^{2+} -selective currents, they also gave rise to similarly increased highly Ca^{2+} -selective currents that were activated by store depletion. Such a mixed selectivity in their mode of activation is entirely inconsistent with the native channels and, instead, suggests that such constructs generate some form of hybrid CRAC/ARC channel. Subsequently, additional experiments revealed that the functional ARC channel is, in fact, a pentameric structure formed from three Orai1 subunits and two Orai3 subunits (Figure 3). Expression of pre-assembled concatenated pentameric constructs with this composition resulted in large arachidonic acid-activated Ca^{2+} -selective currents without affecting the corresponding store-operated currents (Figure 3). Critically, the arachidonic acid-activated currents resulting in the expression of these pentameric constructs displayed all the key biophysical and pharmacological features of the endogenous ARC channels, including a high sensitivity to low concentrations (2–4 μM) of exogenous arachidonic acid, insensitivity to 2APB, and even an exclusive dependence on the plasma-membrane pool of STIM1 for their activation (Figure 4). As noted above, this demonstration that the functional ARC channel was a pentameric structure was unexpected, given that it had previously been shown that the functional CRAC channel was a tetramer. It remains to be determined precisely what role, if any, this fundamental difference in the overall structure of the two channels plays in the determination of their individual specific properties and distinct modes of activation.

What Do ARC Channels Do?

The fact that the ARC channels coexist with store-operated conductances in the same cells, and their biophysical properties are generally so similar to the store-operated CRAC channels, raises the obvious question of what their specific role

Figure 3 The functional ARC channel pore is comprised of a heteropentamer of three Orai subunits and two Orai3 subunits. (a) Cartoon illustrating the structural organization of the two Orai heteropentamers that have been shown to duplicate all the features of the endogenous ARC channels. (b) Inward currents, measured at -40 mV, activated by addition of $8 \mu\text{M}$ exogenous arachidonic acid in untransfected cells stably expressing STIM1 (control) are increased 8–10-fold following expression of either the 31113 or 31311 pentamer in the form of pre-assembled concatenated constructs. (c) Representative current–voltage relationships of the arachidonic acid-activated currents in STIM1-stable cells expressing either the concatenated 31113 pentamer (left) or the 31311 pentamer (right). Both display the marked inward rectification and very positive reversal potential seen in the endogenous ARC channels.

might be. The most likely answer was that their role is related, in some way, to their unique store-independent mode of activation and this has turned out to be the case. Thus, it has been demonstrated in various cell types that the ARC channels are specifically activated by the low, physiologically relevant, concentrations of agonists that typically produce Ca^{2+} signals in the form of repeated oscillations of various frequencies. Studies have shown that such oscillatory Ca^{2+} signals are associated with, at most, only a minimal (2–5%) depletion of the intracellular Ca^{2+} stores – levels that would not be capable of inducing activation of the store-operated conductances (see above). Consequently, the available evidence indicates that,

under these conditions, it is the ARC channels that provide the predominant pathway for Ca^{2+} entry. Although occasional arguments to the contrary have been proposed, these have generally relied on pharmacological approaches which are severely limited by the questionable specificity and selectivity of the drugs currently available (e.g., 2-APB), or have involved the application of arachidonic acid at concentrations that are known to induce obvious nonspecific effects on membrane integrity. Clearly, definitive identification of the specific Ca^{2+} entry pathways operating during such oscillatory responses can only come from studies involving the direct electrophysiological analysis of the activated conductance(s). Using this criterion, studies in HEK293 cells, parotid acinar cells, and in pancreatic acinar cells have all confirmed that the only Ca^{2+} entry channel that can be demonstrated to be active under such conditions is the store-independent ARC channel. Such analysis is particularly clear in the parotid and pancreatic acinar cells, as the biophysical properties of the store-operated conductances in these cells are entirely distinct from those of the ARC channels – they are relatively nonselective conductances (most likely reflecting the activity of TRPC channels), displaying relatively linear current–voltage relationships and with obvious outward currents at positive potentials. Moreover, in the case of the pancreatic acinar cells, the precise physiologically relevant concentrations of cholecystokinin, a major endogenous activator of secretion, are known ($10\text{--}20 \text{ pM}$), and studies have demonstrated that the only detectable Ca^{2+} entry conductance activated at these concentrations is the ARC channel.

A recent report has identified a more specific, and potentially highly important, role of the ARC channels as the key player in the release of insulin from pancreatic β cells. Thus, insulin secretagogues such as acetylcholine and cholecystokinin are known to induce the generation of arachidonic acid which, in turn, triggers insulin secretion from islets at low glucose levels and enhances the secretion of insulin mediated by depolarization. The recent study revealed that this action of arachidonic acid did not involve voltage-gated Ca^{2+} channels and instead specifically resulted from the activation of ARC channels in these cells. The ARC channels therefore represent a critical, and previously unsuspected, component of the overall secretagog-induced release of insulin in pancreatic β cells.

Conclusions and Implications

The demonstrated existence of the ARC channels in a range of different cell types, and the store-independent agonist-activated Ca^{2+} entry pathway that they provide, has several important implications. The most obvious and important is that it can no longer be assumed that simply demonstrating that store-operated Ca^{2+} entry is present in a cell (e.g., by addition of thapsigargin) implies that it is the only pathway for the agonist-activated entry of Ca^{2+} entry in that cell. Determination of which specific Ca^{2+} entry pathway is operating under the relevant conditions can only reliably be achieved by the direct measurement, and biophysical analysis, of the conductance(s) active under those conditions. The necessity of such specific identification of the relevant Ca^{2+} entry pathway is only emphasized by the fact that, as discussed above, the ARC channels have been shown to be present in a wide variety

Figure 4 The features of the currents induced by expression of the appropriate Ora1/Orai3 heteropentamers precisely duplicate those of the endogenous ARC channels. (a) Activation of the currents induced following expression of the concatenated 31311 pentamer in STIM1-stable cells occurs at the same low concentrations of exogenous arachidonic acid as that reported for the endogenous ARC channels. Shown are the mean $\pm$ SE of the inward currents at -40 mV activated by the indicated concentrations arachidonic acid. (b) The resulting current–voltage relationships at all concentrations of arachidonic acid display marked inward rectification and very positive ($> +60$ mV) reversal potentials. (c) The arachidonic acid-activated currents in STIM1-stable cells expressing the concatenated 31311 heteropentamer are completely blocked by $5 \mu\text{M}$ gadolinium (Gd^{3+}). (d) Activation of the increased arachidonic acid-induced currents seen on expression of the 31113 and 31311 pentamers is entirely dependent on STIM1 in the plasma membrane. Shown are inward current density at -40 mV in STIM1-stable cells treated with siRNA to STIM1, and transfected with a wild-type STIM1 (white bar), together with the same siRNA-treated cells expressing either the 31311 or 31113 concatenated pentamer, as indicated, after transfection with either an siRNA-resistant wild-type STIM1 (black bars) or with an siRNA-resistant glycosylation mutant STIM1 (gray bars). Reproduced from Mignen O, Thompson JL, and Shuttleworth TJ (2009) The molecular architecture of the arachidonate-regulated Ca^{2+} -selective ARC channel is a pentameric assembly of Orai1 and Orai3 subunits. *Journal of Physiology* 587: 4181–4197.

of different cell types, and their potential to provide a unique, store-independent, route for agonist-activated Ca^{2+} entry in such cells is clear.

An additional point to note is that the simple demonstration of a dependence on STIM1 and/or Orai1 for any particular cellular response or effect is not sufficient to definitively conclude that such a response involves store-operated Ca^{2+} entry, or the activity of CRAC channels, as both STIM1 and Orai1 proteins are also essential for the activity of the ARC channels. Consequently, proposals to target these proteins therapeutically as a means of specifically affecting CRAC channel activity are not valid. In addition, it is clear that caution must be applied to studies involving the simple overexpression of individual components of the overall ARC channel complex and its regulators. Thus, we already know that the ARC channel requires both Orai1 and Orai3 subunits for its formation, but the ability of these subunits to assemble in the appropriate

manner would likely be profoundly impacted by the relative levels of expression of either of these components – resulting channels of unknown composition and/or stoichiometry. In addition to Orai1 and Orai3, the ARC channels also require adequate STIM1 in the plasma membrane for their activation. Limitations in any one of these components would be expected to have significant impact on overall channel activity. Moreover, as discussed above, studies have shown that ARC channel activity is also dependent on a balance between a PKA-dependent phosphorylation which requires an AKAP and a calcineurin-mediated dephosphorylation. Consequently, factors that influence the balance between these opposing actions would likely profoundly impact the resulting entry of Ca^{2+} through the channels, with the obvious effects on the resulting agonist-induced Ca^{2+} signals generated in the cell.

As discussed above, the specific properties and features of the ARC channels suggest that they are uniquely suited to

provide a critical role in agonist-activated Ca^{2+} entry, particularly under conditions where the sustained depletion of intracellular Ca^{2+} stores is either unlikely or inappropriate. Consistent with this, the activity of these channels has been shown to play a key role in important physiological responses of diverse cell types, including the insulin-secreting β cells, and the exocrine cells of the parotid and pancreas. Undoubtedly, as more groups begin to study these channels, additional roles will be revealed.

Glossary

Domain Element of protein molecular structure, with or without known function, which is conserved among different proteins and/or organisms.

GAP Guanine nucleoside triphosphatase (GTPase)-activating protein that accelerates hydrolysis of GTPase-bound guanine nucleoside triphosphate (GTP) to generate inactive GTPase-guanine nucleoside diphosphate (GDP).

GEP Guanine nucleotide-exchange protein or factor (GEF) that accelerates replacement of GTPase-bound GDP by GTP.

GTPase Protein that catalyzes hydrolysis of GTP to yield inorganic phosphate and GDP.

Vesicle Membrane-enclosed intracellular structure, 100–200 nm in diameter, with or without visible coat structure, that can be a vehicle for the transport of molecules to support many kinds of cell functions, for example, secretion, endocytosis, migration, and proliferation.

Molecular Characteristics of Arfs

Arfs or adenosine diphosphate (ADP)-ribosylation factors were first identified, purified, and characterized because of their ability to enhance the cholera toxin-catalyzed ADP-ribosylation of G α s, the guanine nucleoside triphosphate (GTP)-binding protein activator of adenyl cyclase. Arf action in cells requires its controlled alternation between the inactive guanine nucleoside diphosphate (GDP)-bound and active GTP-bound forms. This property enables Arfs to regulate enzyme activities (e.g., phospholipase D (PLD) and phosphatidylinositol 4-phosphate 5-kinase) and to participate in the assembly, organization, and function of multimolecular complexes that affect or regulate dynamic processes of cytoskeletal structure and intracellular transport.

Mammalian (human) ARFs are grouped into three classes, with ARF1, 2, and 3 in class I, ARF4 and 5 in class II, and ARF6 in class III, based on molecular size, amino acid sequence, and gene structure. Yeast *Saccharomyces cerevisiae* has one class III and two class I Arfs. The Human Genome Nomenclature Committee described the Arf family as comprising Arfs, Arls, ARD1 (Trim23), and Sar1. Amino acid sequences of Arfs are highly conserved among species with >65% identity among human, yeast, and *Giardia* Arfs. All Arfs contain the specific sequences and amino acids that serve in GTP binding and hydrolysis. One of the hallmarks of these molecules is the presence of the Rossman fold, a β - α - β structure responsible for nucleotide binding. The availability of high-resolution structures of Arfs permits identification of other regions, such as the internal β -sheet, that distinguish Arfs from other subfamilies of GTPases. Arf structure also determines the specificity of its interactions with other molecules, and thereby its function. Both Arf and SAR1 protein structures differ from those of all other c. 20-kDa GTPases in the presence of an N-terminal extension, which in Sar1 proteins lacks the N-myristoylated glycine present in all Arfs. Fatty acid modification plus the additional amphipathic helix at the N-terminus facilitates membrane association of Arf proteins via interaction with phospholipids as well as proteins. Recently, N-terminal acylation of Arls, which contributes to their interactions with membranous structures, was shown.

ARF-Related Proteins

In both structure and function, Arfs resemble the several subfamilies of c. 20-kDa Ras-like GTPases that include Rho, Rac, Rab, and Rap. Each of these proteins, like the Arfs, has special, specific roles in cells. Many of their actions, effects, and regulatory mechanisms are similar, and may seem to overlap, perhaps because all of these GTPases appear to function by interacting with numerous other molecules, simultaneously or sequentially, to modify their activities in a manner dependent on whether GDP or GTP is bound. Dimerization of ARF1 has been described but differs from that of proteins activated by nucleotide-dependent dimerization (GADs).

Among the Arf-related proteins, are Arf-like proteins or Arls that appear to be more diverse in function and, as a group, differ more in structure than do the Arfs. Sar1 proteins are most similar to Arfs in both function and structure, and are, therefore, included in the Arf-family. The 181-amino-acid sequences of human ARF1 and ARL1 are 56% identical. Other Arls differ much more, and some Arls have important intranuclear roles (e.g., in nucleolus). There is also an ARP (ARF-related protein) and the intriguing 64-kDa ARD1 (ARF domain protein 1), with an 18-kDa Arf domain at the C-terminus. Structurally, ARD1 is a member of the tripartite motif (TRIM) family that exhibits E3 ubiquitin ligase activity and is apparently auto-ubiquitinated *in vitro* after addition of purified recombinant E1, an appropriate E2, ubiquitin, and adenosine triphosphate.

Arf Actions

With GTP bound, all Arfs are activators of the cholera toxin ADP-ribosyltransferase, which is secreted by *Vibrio cholerae*. They also activate the very similar *Escherichia coli* heat-labile enterotoxin (LT) that causes travelers' diarrhea. Allosteric activation of the cholera toxin A subunit (CTA), which is the ADP-ribosyltransferase enzyme, has been repeatedly shown *in vitro*. The effect of Arfs on CTA action in cells, however, is less clear. The capacity to activate CTA and LT distinguishes

Arfs from other GTPases, including the Arf-like Arl proteins. The biochemical and/or catalytic behavior of Arfs can be markedly influenced by specific phospholipids.

Arf-GTP can also activate mammalian PLD and phosphatidylinositol kinases that act on phospholipids critical in cell signaling. PLD-catalyzed hydrolysis of phosphatidylcholine produces phosphatidic acid, a molecule that alters the physical properties of membranes and also binds specific receptors to initiate signaling. Phosphorylation of phosphatidylinositol 4-phosphate by an Arf-activated kinase likewise contributes to localized modification of membrane composition and, thus, the molecular interactions that can be vitally important in properly controlling cell functions.

The Arf molecule differs dramatically in shape depending on whether GDP or GTP is bound. Arf activation by GTP binding results from movement of the N-terminal helix and its N-myristoylated glycine away from a position close to the Arf molecule surface, where it rests when GDP is bound. This alters, of course, its interaction with other molecules and enables Arf-GTP to bind membranes more effectively than does Arf-GDP (Figure 1). Membrane-bound active Arf-GTP then recruits adaptor and coat proteins to initiate vesicle formation and cargo loading. Arf function in vesicular trafficking probably involves interactions with phospholipids, as well as with proteins, whether the result is the activation of an enzyme, for example, PLD, or initiation of vesicle formation

when membrane-bound Arf-GTP begins assembly of proteins and lipids that will become vesicle coat and content. Among three types of coated vesicles, the Coat Protein Complex I (COPI)- and clathrin-coated structures require, perhaps most often, class I Arfs.

Regulators of ARF Activity

Activation of ARF requires the replacement of bound GDP by GTP, which without specific stimulus occurs very slowly, and is regulated by guanine nucleotide-exchange proteins, or GEPs, that accelerate GDP release and thereby GTP binding (Figure 1). Turn-off (Arf inactivation) results from hydrolysis of bound GTP to generate Arf-GDP, after interactions with a GTPase-activating protein or GAP (Figure 1). Several Arf GEP molecules have multiple interactions with proteins of diverse functions, not all of which have been related to their critical roles as regulatory GTPases in vesicular trafficking pathways. All GEP molecules contain an ~190-amino-acid Sec7 domain, which is responsible for specificity of Arf binding and acceleration of release of Arf-bound GDP that is rapidly followed by binding of GTP (with an intracellular concentration higher than that of GDP).

GEP families are distinguished by overall molecular size and structures of functional sequences outside of the Sec7 domain, as well as by sensitivity of Arf-activation to inhibition by brefeldin A (BFA). BFA is a fungal fatty acid metabolite first used experimentally as an inhibitor of viral replication, and later shown to inhibit protein secretion via specific pathways of intracellular vesicular trafficking. BFA-inhibited GEPs include mammalian BIG1, BIG2, BIG3, and GBF1, as well as the yeast Sec7, Gea1, Gea2, and the *Arabidopsis* GNOM. The structures of molecular complexes formed by ARF GEPs and Arfs with and without BFA and the unusual complex of ARF-GDP associated with BFA, and fostered the idea of a specific GEP effectively locked by the additional interactions with BFA. Resulting uncompetitive BFA inhibition, which suggested development of novel therapies, is reversed by decreasing BFA concentration and release of complex-bound BFA (Figure 1).

Among several known BFA-insensitive GEPs, the family of four human c. 47-kDa cytohesins appears to be the largest. These molecules contain a central Sec7 domain responsible for Arf activation, followed by a pleckstrin homolog (PH) domain, which binds phosphatidylinositol phosphates with notable specificity, contributing to intracellular localization. Cytohesins are of interest as cell-extracellular matrix (ECM) adhesion molecules and regulators of cell signaling. Cytohesin-1 had been identified and cloned because of its function in adhesion of lymphocytes to the extracellular matrix (hence the name) before its role in ARF activation was recognized. The existence of many more GEPs, for example, than the six mammalian (five human) ARFs, is surely critical for accomplishing specific and precise receipt, regulation, integration, and transduction of diverse signals from multiple sources at sites throughout the cell, as well as the adjacent extracellular milieu. Complexity of GEP structures emphasizes the importance of accurate, timely, and spatially limited coordination of cell functions.

Figure 1 (a) Cyclic Arf activation and inactivation catalyzed, respectively, by GEPs and GAPs. Active, GTP-bound Arf, the product of GEP-catalyzed replacement of bound GDP with GTP, associates with membranes, where it recruits adaptor and coat proteins. GAP-accelerated hydrolysis of Arf-bound GTP yields inactive Arf-GDP, which has a lower affinity for membranes and dissociates more readily. ARF6-GDP differs in structure from other Arf-GDPs sufficiently that it tends to be membrane-associated throughout the GTPase cycle. This difference also distinguishes it from class I and II Arfs in GEP interactions. (b) In the BFA-sensitive GEPs, BIG1, BIG2, and GBF1, specific amino acids within the Sec7 domain allow them to form inactive ternary complexes with BFA when Arf-GDP is bound.

Unlike some other ARF GEPs, FBOX8 contains an E3 ligase domain that uses ARF6 as substrate. Exchange Factor for Arf 6 (EFA6) and GEP100/Brefeldin-A-resistant ArfGEP (BRAG2) also contribute to the regulation of ARF6 guanine nucleotide binding, affecting molecular adhesion, nuclear metabolism, and exocytosis in eukaryotic cells. Regulation of Arf inactivation similarly involves multiple families of GAPs that are, such as GEPs, necessary for integrity of Arf GTPase cycle. These proteins contain characteristic zinc-finger elements that accelerate hydrolysis of ARF-bound GTP via a critical arginine residue. The distinctive GAPs, like GEP molecules, contain multiple domains specialized for different functions and interactions, for example, with cytoskeletal structures. Three types of Arf GAPs, (1) GAPs, (2) G-protein-coupled receptor (GPCR)-kinase-interacting proteins (GITs), and (3) Arf-GAP with Src homology 3, ankyrin repeat and PH domains (ASAPs), are recognized. Multiple, individual domains of the ASAP molecules including PH, anchoring, proline-rich, and SH3, enable them to localize at appropriate intracellular sites and to interact specifically with numerous additional molecules to achieve diverse effects on function.

Glossary

Active site A portion of a protein where the catalytic amino acids or associated groups are located and where a binding site for substrate exists.

Chemotherapy Use of compounds to kill disease-causing cells in the human body.

Hemoglobin The oxygen-carrying molecule of the bloodstream found in red blood cells.

Inhibitor A molecule that binds to the active site of an enzyme to block the catalytic activity.

Proteolytic enzyme A protein that has the ability to digest other proteins by cleaving peptide bonds to produce smaller fragments.

Substrate A molecule acted upon by an enzyme to cause a chemical change.

Three-dimensional structure The detailed arrangement of atoms in space for a molecule, usually determined by X-ray crystallography.

Transition-state analog A molecule with a chemical structure that resembles the geometry of the state between a substrate and the products of a reaction.

Zymogen A precursor form of an enzyme, usually larger in size due to the addition of extra amino acid residues; it is also known as a proenzyme.

The Spectrum of Aspartic Proteases in Biology

Historically, aspartic peptidases were first found in the digestive tract of many animals. Pepsin is found in the stomach of most animals with an acidic phase of digestion. A related enzyme, gastricsin, is also present in the stomach and, in some animals, it is the dominant enzyme. Chymosin, a similar enzyme from the fourth stomach of the calf, is responsible for clotting milk when the young animal suckles from its mother. This helps retain the semisolid form of milk proteins in the digestive track for further processing. The presence of an activity was inferred in ancient times when milk was placed in a sack made from the stomach of an animal so that the milk could be transported on long journeys. The travelers found the milk had clotted and realized that something from the stomach lining was causing this to happen. Chymosin is now used to initiate the production of cheese. In some countries, farmers discovered that certain flowering plants also contained a substance that caused milk to clot and these flowers are used in what is termed 'artisanal cheese making'. Other plant enzymes may be involved in digestion of stored seed protein to provide nourishment for a growing seedling. In the world of fungi, many aspartic peptidases have been found. For example, the common baker's yeast, *Saccharomyces cerevisiae*, contains several enzymes in an intracellular organelle called the food vacuole; one of these enzymes is yeast proteinase A.

Due to the progress of genome sequencing projects from 1990 to the present, sequence information is now available for 354 members of the aspartic protease family. They can be related by sequence identities as seen in [Figure 1](#). Representative examples are given for enzymes from animals, plants, fungi, protozoa, insects, and worms. Furthermore, within one organism, different members of the family play different roles. As an example, humans have two enzymes in the

stomach that are involved in the digestion of protein in the diet. In addition, an enzyme in the bloodstream, renin, is involved in regulation of blood pressure by converting a precursor molecule, angiotensinogen to angiotensin I. Subsequent conversion of angiotensin I to angiotensin II has a large effect upon blood pressure, as the latter molecule causes constriction of blood vessels and increases in blood pressure. Within cells, several aspartic proteases are found to play important roles. Cathepsin D in the lysosomes of cells acts to activate other enzymes, prohormones, and growth factors. Cathepsin E, which is found mainly in cells of the lymphoid system, seems to have a function in the response of cells to immunological stimuli. Memapsin, also known as beta-site APP cleaving enzyme (BACE), is involved in the conversion of the β -amyloid precursor protein to a form that can aggregate and cause fibrils that are found in Alzheimer's disease. Several enzymes known as napsins have recently been discovered in humans. Their function is unknown at this point in time. In the genomes of the plant, *Arabidopsis thaliana*, the nematode, *Caenorhabditis elegans*, and the fruit fly, *Drosophila melanogaster*, a similar pattern of multiple potential functions has emerged, as multiple sequences with identities to the aspartic protease family have also been identified.

Structure

Pepsin from the stomach of the pig was one of the first proteins to be crystallized; however, the three-dimensional (3D) structure of three fungal enzymes was reported before the structure of pig pepsin was solved. Since the 1970s several hundred structures have been solved by X-ray diffraction. At this point in time, we can state with certainty that all proteins that have sequence homology of over 40% with the aspartic protease family will have the same overall structure.

Overall Structure

The structure of a typical aspartic protease is shown in **Figure 2** in several views. The structure can be divided in two ways. First, there is a twofold axis of symmetry down the middle of the protein as seen in **Figure 2(a)**. The first 165 amino acids of the protein (the N-terminal domain) are an independent folding unit that is mostly composed of β -strands and very little α -helical structure. The last 165 amino acids (the C-terminal domain) are also an independent folding unit with exactly the same folding pattern. The active site cleft is located between the two domains and on one side of the molecule. Each domain contributes to the surface of the cleft, which either binds substrates for cleavage or acts as inhibitors that block cleavage. The two halves of the enzymes are believed to have arisen by a gene duplication event before divergence into the different forms shown in **Figure 1**. A second way to analyze

the structure has the same division as described above, and also considers the β -sheet shown at the bottom of **Figure 2(b)** as an independent unit comprised of β -strands from each of the two domains. In either analysis, all the known structures are highly similar in structure. Some variation is seen in the relative orientation of the two (or three) domains with respect to each other. In addition, some variability is provided by the length of some of the β -hairpin loops that impinge on the active-site cleft. This provides diversity in the active site-binding characteristics of each enzyme, which could be involved in the specific function of each member of the family.

Catalytic Residues

Each of the two domains (N-terminal and C-terminal) provides one aspartic acid; these two amino acids are located in

Figure 1 Diagrammatic representation of the relationship among several major classes of aspartic proteinases. The number at the top of each division point is the percentage identity between all species below the line. Organism names are given in italics inside parentheses and specific enzyme names are given inside square brackets. Note that different organisms are seen in different points in the diagram. This is due to the fact that different enzymes within one species play different functional roles. This figure was prepared using the program Pymol.

Figure 2 Representation of the 3D structure of a typical aspartic protease. The flat arrows represent β -strand structure and the spiral shapes represent α -helices. These elements are from the backbone only and do not show the complete structure of the protein. (a) View of the enzyme looking end-on into the active site cleft at the top. In this representation, the N-terminal domain is colored orange and the C-terminal domain is colored blue. The two catalytic aspartic acid residues are shown in sticks at the bottom of the active site cleft. Above these amino acids one can see an inhibitor molecule bound in the active site. (b) Same orientation as (a), with the N-terminal domain colored orange, the C-terminal domain colored blue, and the β -sheet at the bottom of the molecule colored red. A small connecting loop between the first three strands of the red β -sheet and the second three strands is colored yellow. This figure was prepared using the program Pymol.

the 3D structure at the bottom of the active site cleft; the carboxylic acid functional group of each of the aspartic acid side chains is within 3–5 Å. In the enzyme without bound ligands, a water molecule is hydrogen bonded to the two aspartic acid residues and is the nucleophile that attacks the peptide bond of a substrate held within the active site cleft.

Flap Structure

Another significant feature of all aspartic proteases is a β -hairpin that hangs over the active site cleft. This is frequently referred to as the flap and movement of this is important in the binding of substrates and inhibitors in the active site. Amino acid differences on the flap, when comparing different members of the family, are important in the different activities exhibited by the enzymes.

Proenzyme Structure

Most aspartic proteases are synthesized within cells as inactive precursors known as zymogens or proenzymes. In all known cases, this involves an N-terminal extension of between 35 and 125 amino acids. In cases where the 3D structure has been determined for some of the proenzyme forms, the extra amino acid sequence acts to either block the active site cleft or to pull the two domains apart from one another; in either case, this prevents activity. For many cases, conversion from the proenzyme to the mature enzyme form is self-catalyzed and occurs when the proenzyme moves from a neutral pH condition to a compartment of lower pH. Removal of the N-terminal extension results in a decrease in molecular weight of between 4 and 15 kDa. In a few known cases, the conversion requires a second enzyme.

Diseases

Efforts to understand the structure and function of aspartic proteases have been stimulated by the discovery that many disease processes involve the activity of these enzymes.

Hypertension

As mentioned above, renin is involved in a cascade of reactions that leads to the elevation of blood pressure. While this is a normal function that can increase blood pressure in times of activity of an individual, when the levels of renin activity are slightly out of balance, the effects can be dangerous to health. Studies in animals have shown conclusively that giving a selective renin inhibitor, that is, a compound that will bind to and block the activity of renin without affecting the other aspartic proteases of the human body, has a dramatic effect on blood pressure levels. This area of investigation was extremely important to the study of the whole field of aspartic proteases, as it allowed scientists to develop the tools and strategies to develop selective inhibitors. This has paid dividends in the development of antiviral inhibitors as well as in programs searching for inhibitors against many other family members.

Cancer

High levels of cathepsin D have been observed in areas surrounding tumors in both humans and animals. This has led to the hypothesis that cathepsin D is involved in the invasiveness of cancer cells. However, cathepsin D activity is normally highest at pH values well below that of tissue. Cathepsin D exhibits its activity in the lysosome, where the pH level is believed to be less than 6. In addition, cathepsin D is released when cells break open, so that the excess levels seen in necrotic tissues may be due to cellular decay. Furthermore, in some conditions, excess levels of cathepsin D are due to overloads of the secretory pathway so that the proenzyme form of cathepsin D is released rather than the mature form. Cathepsin D or the proenzyme form may act as a growth factor to stimulate the growth of cancerous cells.

Acquired Immunodeficiency Syndrome

An aspartic protease is part of the causative agent for acquired immunodeficiency syndrome (AIDS), the human immunodeficiency virus (HIV). This protease acts to cut apart a viral polyprotein so that new virus particles can assemble. The HIV protease was the second target against which new antiviral drugs were developed. These compounds have had a major impact on therapy for AIDS.

Malaria

The malaria parasite, *Plasmodium falciparum*, lives during part of its complicated life cycle within human erythrocytes where it degrades hemoglobin for two reasons: one, to provide nutrients in the form of free amino acids for new protein synthesis, and, two, to create space for growth of the parasitic cell. Digestion of hemoglobin is initiated by the action of aspartic proteases. Following the sequencing of the *P. falciparum* genome, it is now known that 10 different aspartic protease genes are present. Four of these are expressed and the proteins are located within a special organelle, the food vacuole. This organelle is equivalent to the lysosome of mammalian cells and a similar vacuole of *S. cerevisiae*. Complete digestion of hemoglobin requires the coordinated activity of cysteine proteases and metallo-proteases as well as the aspartic proteases. Inhibitors of aspartic proteases are able to kill the parasite in culture studies.

Fungal Infections

A number of fungi are known to cause diseases in humans and plants. For example, *Candida albicans* is a common commensal organism, living within the human body but kept in check by a healthy immune system. In situations where the immune system is compromised, due to chemotherapy for cancer or immune suppression to avoid transplant rejection or due to suppression by diseases such as AIDS, *C. albicans* can become a life-threatening systemic infection. The fungus is also known to have a number of aspartic proteases, including several that are secreted into the extracellular environment surrounding the fungal cells. These enzymes are believed to assist in providing nutrients to the fungus by digesting proteins found in the

surrounding environment. Some of these secreted enzymes may work to aid in the invasiveness of the fungus as the infection spreads.

Alzheimer's Disease

The newest target for drug discovery is β -secretase or memapsin. This enzyme acts to cleave the β -amyloid precursor protein at a specific bond, generating a fragment that can become, with further modification by the so-called gamma secretase, a peptide that forms amyloid fibrils. This condition leads to neurofibrillary plaques in the brain, which are a hallmark of Alzheimer's disease. Due to the unique specificity of memapsin, development of specific inhibitors is possible and new therapies for this condition may develop in the next few years.

Inhibitors

Naturally Occurring Inhibitors

Unlike the serine protease family, naturally occurring inhibitors of aspartic proteases are relatively rare. A few have been described in detail and their structural information obtained. By investigating the mechanism of inhibition of these protein inhibitors, it is hoped that new insights into inhibitor design will be found.

Pepstatin

Culture filtrates of the organism *Streptomyces* have been found to contain many interesting compounds. Pepstatin, discovered around 1970, was found to strongly inhibit pepsin and other members of the aspartic protease family. This compound is a relatively nonspecific inhibitor, as it seems to block most members of the aspartic protease class. Pepstatin contains an unusual amino acid, 3-hydroxy-4-amino-6-methylheptanoic acid. The 3-OH group binds to the two catalytic aspartic acids to form a transition-state analog, which provides very tight binding. Because all aspartic proteases have the identical catalytic mechanism, pepstatin is an excellent inhibitor. This compound has been used in many studies of the 3D structure of members of the aspartic protease family and thus provides convenient comparisons between these enzymes. Many synthetic inhibitors, mentioned below, utilize the same concept in the design of selective inhibitors.

PI-3 pepsin inhibitor of Ascaris

The nematode, *Ascaris lumbricoides*, lives within the human digestive tract for a significant part of the life cycle. The digestive tract contains many proteolytic enzymes, including aspartic proteases. The nematode produces several proteins, each of which is able to bind to and inhibit a specific host enzyme. Several inhibitors have been purified to homogeneity, including PI-3. From a purification of the aspartic protease inhibitors, the third fraction had the highest activity in assays of the ability to inhibit pepsin, thus leading to the designation, PI-3. PI-3 is a

protein of 149 amino acid residues. It inhibits pepsins and gastricsins from humans and pigs, and has been shown to inhibit cathepsin E from humans. The structure of PI-3 in complex with porcine pepsin has been determined and it was found that the inhibitor is a rigid protein, which makes contact with pepsin at two points, using a total of about 13 out of the 149 residues. The structure of the inhibitor does not change when interacting with pepsin.

IA-3 yeast protease inhibitor of S. cerevisiae

The yeast *S. cerevisiae* synthesizes a 68-residue protein called IA-3, which is a strong and selective inhibitor of yeast proteinase A. The 3D structure of the complex between the two proteins shows that the inhibitor forms a near-perfect α -helix between amino acids 2 and 34 when it binds to the enzyme, while the inhibitor, when free in solution, has little or no organized structure. The IA-3 inhibitor does not inhibit any other member of the aspartic protease class that have been tested so far and, in fact, is cleaved by several of the other enzymes. The transition from an unstructured protein to a tightly folded one is a unique aspect of this inhibitor. This is an example of an intrinsically unstructured protein.

Synthetic Inhibitors

Due to the importance of aspartic proteases in several disease processes, strong efforts have gone into the design and testing of compounds that could become new drugs for the treatment of disease. In many cases, the observations that pepstatin was a potent inhibitor gave the initial clue to inhibitor design. Thus, the presence of a hydroxyl group within the structure of a new compound is frequently coupled with the variation in the amino acid sequence (for peptide-like compounds), or in the structural groups (for nonpeptide compounds) to create a selective inhibitor. Other variations on the central hydroxyl group include replacements for the peptide bond such as $-\text{CH}_2\text{NH}-$, $-\text{PO}_2-\text{CH}_2-$, and $-\text{CHOH}-\text{CHOH}-$. These replacements have proved to be effective in the development of new inhibitors.

Glossary

Alternative oxidase An ubiquinol oxidase located in the inner mitochondrial membrane, which accepts electrons from reduced ubiquinone and reduces oxygen to water. During this process, no protons are translocated across the inner mitochondrial membrane.

Nonphosphorylating pathway A route of electron transfer with no concomitant translocation of protons across the inner mitochondrial membrane; hence, this route of electron flow does not contribute to the proton-motive force.

Nonphosphorylating reduced nicotinamide adenine dinucleotide phosphate (NAD(P)H) dehydrogenase(s) Enzymes that accept electrons from NADH or NADPH and reduce ubiquinone, a mobile lipophilic electron carrier in the inner mitochondrial membrane with no consequent proton translocation across the membrane.

Proton-motive force Refers to the proton gradient that is established across the inner mitochondrial membrane during electron transfer through complexes I, II, and IV, often referred to as $\Delta\mu_{H^+}$ or pmf.

Adenosine triphosphate (ATP) is the energy carrier of the cell and in eukaryotic cells is synthesized via photosynthesis and respiration. Within respiration, there is a low level of ATP synthesis associated with glycolysis in the cytoplasm; however, the majority of ATP is synthesized via oxidative phosphorylation which occurs within mitochondria, specifically via the operation of an electron transport chain (ETC) in the inner mitochondrial membrane. In mammals, flux through the respiratory pathway is tightly regulated by the ATP/adenosine diphosphate (ADP) ratio or adenylate energy charge of the cell. Plants, unlike mammals, must synthesize all of their cellular components. In plants, the presence of a nonphosphorylating pathway in the mitochondrial ETC and an uncoupler protein in the inner membrane overcomes this restriction by adenylate control. In plants, respiration not only is important for energy production but also has a major role in biosynthesis and anabolic reactions, in programmed cell death, and, more recently, has been implicated as stress response signaling sensor.

Mitochondrial ETC in Plants

Sucrose and starch are converted to metabolites that feed into the early steps of glycolysis which occurs in the cytoplasm. The end products of glycolysis in plants can be either pyruvate or malate, the latter being formed by the action of phosphoenol pyruvate carboxylase and malate dehydrogenase, which together bypass pyruvate kinase. Once within the mitochondrial matrix, pyruvate is metabolized by pyruvate dehydrogenase and the enzymes of the citric acid cycle. Being a substrate for mitochondrial malate dehydrogenase, malate can either feed into the citric acid cycle or be metabolized to pyruvate via nicotinamide adenine dinucleotide (NAD)-malic enzyme. There must be a balance between these processes, because of the poor forward equilibrium of malate dehydrogenase, the accumulation of oxaloacetate would prevent further malate metabolism. The net result of these reactions is the production of NADH and FADH₂ (via succinate dehydrogenase). During a

turn of the citric acid cycle, one ATP is produced directly by substrate-level phosphorylation, not guanosine triphosphate (GTP) as in mammalian mitochondria. Matrix NADH is oxidized by the ETC and more ATP is produced via oxidative phosphorylation.

Oxidative phosphorylation occurs via the interaction of large lipoprotein complexes of the ETC and smaller mobile electron carriers found in the inner mitochondrial membrane (Figure 1). NADH is oxidized by complex I, which donates its electrons to a mobile lipophilic electron carrier, ubiquinone. Complex II or succinate dehydrogenase also donates electrons to the ubiquinone pool. Reduced ubiquinone (or ubiquinol) is oxidized by complex III via the Q-cycle and reduces the mobile peripheral protein cytochrome *c*. By interacting with complex IV (cytochrome oxidase), the electrons carried by cytochrome *c* are donated to the terminal electron acceptor, oxygen. During these electron-transfer events, protons are translocated from the matrix side of the inner membrane to the intermembrane space at complexes I, III, and IV, thus establishing the proton-motive force (pmf or $\Delta\mu_{H^+}$). If ADP is bound to the F₀F₁-ATPase in the inner membrane, then protons pass through this complex and the energy within the pmf is used to synthesize ATP. Once ATP is synthesized, it is then exported out of the matrix in exchange for another ADP via the adenine nucleotide translocase. Thus, the flow of electrons and, hence, oxygen consumption are tightly under control of cellular ADP levels. This is called acceptor or adenylate control.

In plant mitochondria, additional protein complexes are found associated with this ETC. They are distinct from complexes I to V, in that they participate in the transfer of electrons from NADH to oxygen, but do not contribute to the pmf. These enzymes are the alternative or nonphosphorylating reduced nicotinamide adenine dinucleotide phosphate (NAD(P)H) dehydrogenases (NDE and NDI), which donate electrons to the ubiquinone pool and the alternative oxidase (AOX), which accepts electrons from reduced ubiquinone (Figure 1).

Evidence for the alternative nonphosphorylating NAD(P)H dehydrogenases comes from the ability of isolated plant

Figure 1 A schematic representation of the routes of NAD(P)H oxidation and the electron transport chain (ETC) of plant mitochondria. NDI refers to internal matrix-facing nonphosphorylating NAD(P)H dehydrogenase, and NDE refers to external cytosolic nonphosphorylating NAD(P)H dehydrogenase. UCP refers to the uncoupling protein. Reproduced from Rasmusson AR, Soole KL, and Elthon TE (2004) Alternative NAD(P)H dehydrogenases in plant mitochondria. *Annual Review of Plant Biology* 54: 23–39.

mitochondria to oxidize externally supplied NAD(P)H, which cannot pass through the inner membrane. The external cytosolic-facing NAD(P)H dehydrogenase (NDE) feeds directly into the ubiquinone pool, as external NAD(P)H oxidation has an ADP/O ratio equivalent to succinate of less than 2.0. Matrix NADH oxidation in plants has a component which is insensitive to inhibition by the complex I inhibitor, rotenone. This oxidation is catalyzed by internal inner mitochondrial membrane transdehydrogenases (NDI). The rotenone-insensitive alternative matrix NADH oxidation has an ADP/O ratio also similar to succinate indicating that NDI also feeds electrons into the ubiquinone pool, bypassing proton pumping at complex I. The AOX is a cyanide and antimycin A-resistant ubiquinol oxidase that catalyzes the reduction of oxygen to water with electrons from ubiquinol and, thus, bypasses the proton pumps at complexes III and IV. Sequence analysis of the genes putatively encoding NADH(P)H dehydrogenases in various plant species has separated this gene family into three subfamilies, NDA, NDB, and NDC, based on their homology to the yeast and bacterial gene sequences. There is functional evidence that links NDA to NDI activity and the NDB gene family to NDE activities. It is as yet unknown whether NDC encodes an NDI- or NDE-like activity.

Thus, it is possible to have electron transport/transfer with no ATP synthesis in plant mitochondria. Therefore, due to the bypasses that exist around key regulatory sites in glycolysis, plant respiration can be totally independent of respiratory control, which gives plants great metabolic flexibility. This flexibility, which results in the loss of adenylate control of respiration by the energy status of the cell, can theoretically

allow the release of biosynthetic intermediates from the respiratory pathway, independent of energy charge of the cell. This role of the nonphosphorylating pathway is hypothesized and has not been clearly demonstrated *in vivo*.

Substrates for ATP Synthesis

The plant mitochondrial ETC can oxidize matrix NADH and NADPH to a much lesser extent. The source of this NADH is from pyruvate dehydrogenase and the citric acid cycle, and plants have the full complement of these enzymes in addition to other unique enzymes. The presence of matrix pools of NADPH is indicative of the mitochondria's anabolic role. NADP-dependent enzymes involved in folate and thymidylate synthesis such as NADP-dihydrofolate reductase and methylene tetrahydrofolate dehydrogenase have been found in plant mitochondria and their continued operation requires the turnover of the NADPH generated via NDI2. Apart from NAD-dependent isocitrate dehydrogenase, there is also another NADP-dependent form in the matrix; however, its role in plant metabolism is not yet clear. Additionally, via the action of a soluble transhydrogenase detected recently in pea leaf matrix, the mitochondrial oxidation of any strictly NAD-linked substrates such as pyruvate would also be able to produce NADPH.

Another unique enzyme found in plant mitochondria is glycine decarboxylase, which generates NADH in the matrix, is part of photorespiratory cycle and is important in photosynthetic metabolism. It is accepted that the mitochondrial

ETC operates in the light, and that ATP synthesis in the light is not exclusively generated from photosynthesis. Evidence indicates that glycine oxidation is linked to a nonphosphorylating NADH dehydrogenase, such as NDI. Recently, it has been shown that NDI is regulated at the transcriptional level by light, at least in potato leaf, suggesting a link between nonphosphorylating enzymes and photorespiratory metabolism.

Plant mitochondria also have the capacity to oxidize cytosolic NADH and NADPH via the enzymes NDE1 and NDE2. Thus, ATP synthesis can also occur from the recycling of cytosolic NAD(P)H.

Inhibitors of ATP Synthesis

There are a multitude of inhibitors that act on specific components of the ETC and the use of many of these has been invaluable in elucidating the composition of the respiratory chain in different species (Table 1).

The two most common and specific complex I inhibitors are rotenone and piericidin A, both inhibitors block electron flow between the final iron-sulfur center and ubiquinone. However, they display different inhibition kinetics and it is postulated that the transfer of electrons to quinone may involve more than one quinone-binding site, similar to those observed in complex III. Many other inhibitors of mammalian complex I have been discovered, such as aurachin A and B, thiagazole, phenoxan, and aureothin, and many are likely to inhibit plant complex I; however, their efficacy and specificity have not been demonstrated.

Table 1 Specific inhibitors of plant respiratory enzymes

Respiratory protein	Inhibitor	Site/mode of action
Complex I	Rotenone	Blocks between FeS
	Piericidin A	Cluster N2 to quinone
Complex II	Malonate	Competitive substrate
	Thenoyltrifluoroacetone (TTFA)	Blocks FeS cluster S3
Complex III	Antimycin A	Quinone binding (N side)
	Myxothiazol	Quinone binding (P side)
	Stigmatellin	Quinone binding (P side)
Complex IV	Cyanide	Competitive inhibitors of
	Azide	O ₂ -binding site
	Nitric oxide	
Complex V	Oligomycin	Binds to OSCP-subunit
	Venturicidin	Proton translocation (c-subunit)
NDE1 (external NAD(P)H)	DPI	
	Calcium chelators	
NDE2 (external NADH)	Calcium chelators	
NDI1 (internal NADH)		
NDI2 (internal NAD(P)H)	Calcium chelator	
	DPI	
Alternative oxidase	<i>n</i> -Propylgallate	
	SHAM	

Relatively few inhibitors of plant complex II have been described (Table 1), the most widely used is the competitive substrate inhibitor malonate; however, several new complex II inhibitors that are potential fungicides or pesticides have been reported recently.

The two most significant specific complex III inhibitors are antimycin A and myxothiazol, which are specific to the N-side and P-side quinone-binding sites, respectively, and have been important for developing models of the Q-cycle which is involved in proton translocation by complex III.

Complex IV is inhibited by a variety of competitive inhibitors of the oxygen-binding site, such as cyanide and azide. The most interesting of these is the rapid and reversible inhibition by nitric oxide, which may play an important role in regulation of oxidative phosphorylation.

There are several chemical inhibitors of ATP synthase (Table 1), the most prominent being oligomycin, which is a specific inhibitor of F-type ATP synthases found in a variety of organisms. Apart from the chemical inhibitors, there are also inhibitor proteins, which play a role in regulating the activity *in vivo*. The most characterized is the mammalian inhibitor protein (IF1), whose conformation and inhibitory activity change in response to pH. Proteins with low homology to IF1 have been found in plants, and although they can inhibit ATP synthetase activity, they do not appear to be regulated by pH. More recently, a class of phosphoserine/phosphothreonine-binding proteins, called the 14-3-3's, have been identified in plant mitochondria and shown to regulate the ATP synthetase activity.

There are several inhibitors of the alternative NAD(P)H dehydrogenases, while a few show differential selectivity between the various alternative NAD(P)H dehydrogenases many of these such as platanetin, 7-iodo-acridone-4-carboxylic acid, dicumarol, hydroxyflavaones, and sulfhydryl reagents can inhibit all of the alternative NAD(P)H dehydrogenases. Interestingly, many of these were originally reported as specific inhibitors of particular alternative NAD(P)H activities. The most effective selective inhibitors are calcium chelators such as egtazic acid, which are potent inhibitors of the external and NADPH-utilizing enzymes, which have a calcium requirement, and diphenyleneiodonium, which is more effective at inhibiting NADPH-utilizing enzymes compared to NADH-utilizing enzymes (Table 1). Salicylhydroxamic acid (SHAM) and *n*-propylgallate are the most prominent inhibitors of the AOX, the latter being more specific as SHAM can also effect other enzymes of oxidative metabolism such as peroxidases, lipoxygenase, and xanthine oxidases.

Uncouplers of ATP Synthesis

Chemical Uncouplers

Oxidative phosphorylation in plants is sensitive to chemical uncouplers such as dinitro phenol and carbonyl cyanide *p*-(trifluoromethoxy)phenylhydrazone (FCCP) which dissipate the $\Delta\mu_{H^+}$ by carrying proteins across the inner membrane, thus equilibrating the proton gradient. In heterotrophically grown tobacco-suspensions cells, cellular respiration is increased by the addition of the uncoupler, FCCP; therefore, under these conditions respiration is substrate limited.

Nonphosphorylating Respiration

Plants have the capacity to uncouple respiration and ATP synthesis using naturally occurring enzymes such as the alternative NDE and NDI, and AOX. Therefore, the level of coupled respiration will be dependent on the level and activity of these alternative ETC enzymes.

Alternative NAD(P)H dehydrogenases

In plants, complex I has a much better affinity for NADH than NDI. This suggests that the latter route of electron flow will only be active when the matrix concentration of NADH is high. This has been clearly demonstrated in tissues such as potato, which lose NAD from their mitochondrial matrix during long-term storage. In NAD-depleted mitochondria, the rate of electron flow through NDI was markedly reduced, that is, malate oxidation in isolated mitochondria was totally sensitive to rotenone; however, this could be overcome if the mitochondria were reloaded with NAD from the bathing media. NAD enters via a specific transporter on the inner membrane. It is not clear if this level of regulation occurs *in vivo*. One of the NDI enzymes that uses NADPH as a substrate is calcium dependent and could be regulated via matrix calcium levels. One question is whether these alternative pathways operate as overflow for complex I or operate simultaneously during respiration *in vivo*. In a mutant where expression of one of the NDI enzymes was eliminated, the total respiration was reduced, which suggests that NDI contributes to respiration in presence of ADP along with complex I. Both the NDE enzymes are dependent on calcium for maximal activity. It has been suggested that electron flow through the NDE can be regulated by alteration of the local calcium concentration which can be facilitated by polyamines that occur naturally in plant cells, for example, spermine and spermidine.

Alternative oxidase

For many years, it was thought that the AOX acted as an overflow, only being used when there was an excess of reduced ubiquinone and the cytochrome pathway (via complexes III and IV) was saturated. It is now known that this is not the case, and that AOX and cytochrome pathway can operate simultaneously. Thus, the level of ATP synthesis will rely on the regulation of AOX. AOX can be regulated at both the transcriptional and posttranslational level. AOX exists as a monomer or dimer, with the monomeric form being most active. Further, AOX is activated by organic acids such as pyruvate. Pyruvate is the end product of glycolysis and, thus, this activation can act as a positive feedforward mechanism of control when glycolytic flux is high. AOX is induced upon inhibition of the complexes III and/or IV and also under various environmental stresses. It is thought that the expression of AOX is an attempt by the plant to have a flexible control of ATP synthesis and to maintain growth rate homeo-

stasis. It is also thought to be part of the cell's defense against oxidative stress, as increased flux through the ETC would prevent the accumulation of high-energy electrons in the respiratory pathway, which could react with oxygen to form harmful, reactive oxygen species. More recently, reverse genetics experiments with transgenic plants under- and overexpressing AOX in plants have led to the proposal that a core role of AOX may be to modulate the strength of a stress-signaling pathway from the mitochondrion that controls cellular responses to stress. Thus, AOX could be acting to provide a degree of signaling homeostasis from the mitochondrion, influencing cell-wide stress response.

Uncoupling protein

In addition to AOX, plants also have uncoupling protein (UCP), which mediates proton reuptake across the inner membrane (Figure 1). This activity is activated by free fatty acids and inhibited by pyridine nucleotides. UCP is active during respiration in the presence of excess ADP when the free fatty acid concentration is $\sim 4 \mu\text{M}$, and, thus, can divert energy from oxidative phosphorylation, impacting on the capacity for ATP synthesis. There is a reciprocal regulation between UCP and AOX as free fatty acids inhibit AOX activity, similarly 4-hydroxy-2-nonenal, a product of lipid oxidation, has been shown to inhibit AOX but stimulate UCP. However, a precise understanding of the integration and regulation of nonphosphorylating respiratory pathway, UCP and ATP synthase, remains a major research challenge.

ATP Synthesis: Mitochondrial Cyanide-Resistant Terminal Oxidases

J N Siedow, Duke University, Durham, NC, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Aerobic respiration The biochemical process whereby reduced organic compounds are completely oxidized in three stages, glycolysis, the tricarboxylic acid (TCA) cycle, and the mitochondrial electron transfer chain with the free energy released used to drive the synthesis of adenosine triphosphate (ATP).

Alternative pathway The mitochondrial electron transfer pathway that goes via a cyanide-resistant, alternative oxidase (AOX) and transfers electrons from the ubiquinone pool to molecular oxygen without storing any of the released free energy in the form of a proton gradient.

Cytochrome (cyt) pathway The mitochondrial electron transfer pathway that goes from the ubiquinone pool to molecular oxygen via complex III and complex IV (cytochrome *c* oxidase) and is coupled at each complex to

the transport of protons across the membrane to produce a proton gradient that subsequently drives the synthesis of ATP.

Diiron carboxylate protein Any member of a large family of proteins that contain a diiron active site formed by a four-helix bundle, two helices of which provide ligands to the two iron atoms via an E-X-X-H sequence motif and two of which each provide a single carboxylate ligand (i.e., Glu or Asp) to the irons. Family members include the R2 subunit of ribonucleotide reductase and the hydroxylase subunit of methane monooxygenase.

Reactive oxygen species (ROS) Any of several highly reactive chemical species that can be formed following the reduction of molecular oxygen (O_2), including superoxide anion (O_2^-), hydrogen peroxide (H_2O_2) and hydroxyl radical ($OH^\cdot$).

The Uniqueness of Plant Mitochondria

Plant mitochondria, like those of all other eukaryotes, contain a standard set of protein complexes that make up the electron transport chain in the inner mitochondrial membrane, complexes I–IV (Figure 1). This electron transfer chain functions as the third stage of aerobic respiration, whereby reductants reduced nicotinamide adenine dinucleotide (NADH) and reduced flavin adenine dinucleotide ($FADH_2$) generated during operation of the tricarboxylic acid (TCA) cycle in the mitochondrial matrix are oxidized and the resulting electrons transferred to molecular oxygen. The free energy released during this electron transfer is used to translocate protons across the inner membrane from the mitochondrial matrix to the intermembrane space at complexes I, III, and IV, forming an electrochemical proton gradient across the inner membrane. Another inner membrane protein complex, complex V (adenosine triphosphate (ATP) synthase), provides a path for protons to move back into the matrix and, in the process, couples the release of the energy stored in the proton gradient to the synthesis of ATP from adenosine diphosphate (ADP) and P_i . The terminal reaction of the electron transfer chain is the reduction of O_2 to H_2O by complex IV (cytochrome *c* oxidase, COX). This standard electron transfer pathway is frequently termed the 'cytochrome' (cyt) pathway because of the cytochromes present in complexes III and IV and cytochrome *c*. Specific inhibitors of each of the mitochondrial complexes are known. For example, rotenone inhibits complex I, antimycin A inhibits complex III, and cyanide inhibits COX.

In addition to the standard cyt pathway, mitochondria in plants contain a variety of additional electron transport proteins that impart flexibility to the system because they can operate without being coupled to ATP synthesis (Figure 1). On the electron input side of the ubiquinone pool are two sets of reduced nicotinamide adenine dinucleotide (phosphate)

(NAD(P)H) dehydrogenases. One pair of dehydrogenases is found on the outside of the inner mitochondrial membrane, allowing mitochondria to oxidize cytoplasmic NADH or NADPH, respectively. A second set exists on the inner surface of the inner membrane and oxidizes matrix derived NAD(P)H. These dehydrogenases do not contribute to proton gradient formation during electron transfer and therefore are able to operate unconstrained by it, unlike proton-pumping components such as complex I whose activity will be impaired as the size of the proton gradient increases. These alternative dehydrogenases are also insensitive to complex I inhibitors such as rotenone. Electrons derived from the oxidation of NAD(P)H by these dehydrogenases are transferred to the common pool of ubiquinone that also serves as the electron sink for complexes I and II (Figure 1).

Cyanide-Resistant Respiration

Plant mitochondria (and those of many other organisms cf. below) also have an additional electron transport branch downstream of the ubiquinone pool due to the presence of a second terminal oxidase in addition to COX. This alternative oxidase (AOX) is a ubiquinol:oxygen oxidoreductase that accepts electrons from reduced ubiquinol and subsequently reduces O_2 to H_2O (Figure 1). AOX activity is resistant to cyanide and other traditional inhibitors of COX but is specifically inhibited by salicylhydroxamic acid (SHAM) and *n*-alkyl gallate, neither of which affects the cyt pathway. An important feature distinguishes the two oxidase pathways. Electron flux downstream of the ubiquinone pool through the cyt pathway drives proton gradient formation at complexes III and IV, but no proton gradient formation occurs during operation of the AOX pathway. Thus, AOX would appear to be a wasteful enzyme from an energetic standpoint, eliminating a primary

Figure 1 Schematic representation of the plant mitochondrial electron transfer chain.

mitochondrial function during aerobic respiration, coupling the oxidation of the reductants generated during the operation of glycolysis and the TCA cycle to the synthesis of ATP.

Historically, AOX has been associated with all higher plants, most algae, many fungi, and some protozoa. It was also long felt to be the case that no prokaryotes or metazoans (animals) contained this oxidase. More recently, the advent of large-scale genome sequencing has led to the discovery of the AOX protein in an ever-expanding number of organisms, including many proteobacteria and at least eight phyla of metazoans. At present, arthropods and vertebrates appear not to have AOX, and it also has yet to be found in Archaeobacteria. Among protozoa, AOX is noteworthy for its important role in the bloodstream form of the organism responsible for African sleeping sickness, *Trypanosoma brucei*.

Contemporary understanding of AOX can be traced to the development of an antibody against the plant AOX in 1989. The availability of this antibody led to the first isolation of a plant AOX gene and now hundreds of AOX sequences across a wide range of organisms (cf. above) are known. In eukaryotes, AOX is nuclear-encoded, and in plants, fungi, and protozoa, it often occurs as a small gene family (e.g., five genes in *Arabidopsis* and three in soybean), which produces proteins from 32 to 35 kDa (~285 amino acids). More recently, characterization of the gene associated with a mutation leading to a defect in chloroplast biogenesis, IMMUTANS, identified a chloroplast protein having sequence similarity to AOX. IMMUTANS also functions as a quinol oxidase, leading to its characterization as a plastid terminal oxidase (PTOX). It has been shown to participate in a desaturation step during carotenoid biosynthesis in chloroplasts. As prokaryotic genome sequencing has progressed, AOX homologs of unknown function have now been identified in many α -proteobacteria and PTOX homologs have

been reported in several cyanobacteria, respectively. Phylogenetic analyses of the bacterial and eukaryotic sequences suggest that AOX and PTOX arose from a common prokaryotic ancestor, but the two activities diverged prior to the endosymbiotic events that gave rise to mitochondria and chloroplasts.

AOX Structure

AOX is an integral inner membrane protein, but early attempts to purify and characterize it were hampered by the instability of the protein following its solubilization from the membrane and the lack of any apparent useful spectroscopic features to follow, including no visible (>350 nm) absorption spectrum or electron paramagnetic resonance (EPR) spectral features in either its fully oxidized or reduced states. The observation that iron was required for induction of AOX activity in the fungus *Hansenula anomala* originally led to the suggestion that the active site contained iron. AOX sequence analyses later revealed the presence of conserved iron-binding motifs found in members of the family of diiron carboxylate proteins that include the R2 subunit of ribonucleotide reductase and the hydroxylase subunit of methane monooxygenase. This led to the initial development of a model of the AOX active site that contained a four-helical bundle forming a hydroxo-bridged diiron binding site. The suggestion of a hydroxo-bridged iron center accounted for the absence of any visible absorbance, analogous to the diiron center in methane monooxygenase. Subsequently, an EPR signal associated with a mixed valence Fe (II)/Fe(III) hydroxo-bridged binuclear iron center was reported for an *Arabidopsis thaliana* AOX expressed in *Escherichia coli*, providing direct spectral evidence for the diiron carboxylate nature of the AOX and, by analogy, the PTOX active site.

Over time, the AOX structural model has been refined. As currently envisioned (**Figure 2(a)**), the C-terminal two-thirds of the AOX protein comprise a four-helical bundle that makes up the diiron binding scaffold. Two short hydrophobic helical regions anchor the protein in the inner leaflet of the bilayer, with the bulk of the protein protruding into the mitochondrial matrix. The C-terminal region is relatively conserved among all AOXs, showing 85–90% sequence similarity among plants and over 55% similarity between plants and fungi.

While the C-terminal two-thirds of the AOX protein is responsible for forming the catalytic diiron site, the structure of the N-terminal third of the protein is unknown. When plant and fungal amino acid sequences in this region are compared, there is considerable sequence conservation within each organismal type but marked sequence variability between them. Within the N-terminal third of the plant AOX, there is a highly conserved block of about 38 amino acids that includes a

regulatory cysteine (cf. below). Fungal sequences initially align with plant sequences right after this block. From that point on, the plant and fungal sequences are highly similar with two exceptions: (1) an insertion of 20–25 amino acids unique to fungi just before the first of the four iron-binding helical regions and (2) an extension of the fungal C-terminus, 20–50 amino acids beyond that found in plants. AOX sequences in protozoa are more similar to the fungal AOX than they are to that of plants.

In plants, chemical cross-linking studies have established that AOX exists in the membrane as a dimer consisting of two AOX monomers (**Figure 2(b)**). However, the fundamental unit of catalytic activity based on radiation-inactivation analysis is the monomer. Consistent with the latter observation, AOXs dimers are not universal; cross-linking studies with AOX in fungi and protozoa have established that they both exist in the membrane as monomers.

Figure 2 Diagrammatic representation of the structure of AOX. (a) AOX monomer, (b) dimeric AOX structure found in plants. The two red spheres in (a) represent the diiron center (shown in black in (b)). The inner mitochondrial membrane is delimited by the set of parallel horizontal lines.

Biochemical Regulation of AOX Activity

While the N-terminal third of the AOX protein is less well characterized structurally than the remainder of the protein, this region has been found to confer regulatory features on the plant AOX. The plant AOX homodimer can exist in two forms, an oxidized state where the two monomeric subunits are covalently linked by an intermolecular disulfide bond and a reduced state where the AOX remains dimeric but the disulfide is reduced to its component sulfhydryls (**Figure 3**). In the oxidized state, AOX is inactive. When the disulfide is reduced, AOX remains inactive but now has the ability to become activated in the presence of an α -keto acid, such as pyruvate (**Figure 3**). In the absence of α -keto acids, AOX has essentially no activity. AOX is activated by α -keto acids through reaction with a cysteine residue to form a thiohemiacetal. Site-directed mutagenesis of AOX has established that a single cysteine residue (termed CysI, the more N-terminal of two highly conserved cysteines located in the N-terminal third of the protein (**Figure 2(a)**)) is responsible for both the inactivating disulfide bond and interaction with α -keto acids to form the thiohemiacetal that activates AOX (**Figure 3**). CysI appears in the middle

Figure 3 Biochemical regulation of plant AOX by the combined effects of reduction/oxidation of the redox-active sulfhydryl/disulfide bond and the reaction with α -keto acids to form an activating thiohemiacetal.

of the conserved block of 38 amino acids found in plant AOXs. Given the close proximity of the two regulatory CysIs on adjacent AOX monomers, it appears that AOX activation following α -keto acid binding results from a conformational change brought about by charge repulsion between the resulting two proximal negative charges (Figure 3).

The regulatory features outlined above provide a facile mechanism for activating AOX when electron flow through the standard cyt pathway is restricted. Under such conditions, electron transfer would slow down leading to a buildup of reductant in the mitochondrial matrix. The more reduced environment in the matrix would bring about the reduction of the AOX regulatory disulfide, possibly via reduced thioredoxin, which is found in the plant mitochondrial matrix. As electron transfer becomes limiting, TCA cycle activity would become restricted causing pyruvate concentrations to increase, activating the AOX through a feed-forward regulatory system.

Biochemical regulation of AOX activity in fungi and protozoa is not as well characterized as in plants, but purine nucleotides, particularly guanosine monophosphate (GMP), adenosine monophosphate (AMP), and ADP, are known to markedly stimulate AOX activity in fungi and protozoa. No stimulation of AOX activity by α -keto acids has been seen in fungi.

Physiological Role(s) of AOX

The fact that the alternative pathway wastes much of the free energy released during aerobic respiration must be related to its metabolic role. AOX has been found in all higher plants but there is only one instance where its role is clearly established, thermogenesis during flowering in certain members of the plant family Araceae. Just prior to pollen release, high levels of mitochondria found in club-like structures on the floral inflorescence undergo very high rates of respiration, heating up the inflorescence and volatilizing aromatic compounds that serve to attract pollinating insects. Mitochondria isolated from this thermogenic tissue have extremely high levels of AOX protein, allowing the high rates of respiration without having to synthesize and use comparable amounts of ATP.

Most plant tissues do not respire at rates sufficient to support even modest thermogenesis, so that they cannot represent its primary function in the vast majority of plant tissues. Because AOX is not involved in proton gradient generation, its activity is independent of the size of the gradient, unlike the cyt pathway, whose activity will be impaired as the proton gradient increases. Therefore, the AOX is in a position to oxidize mitochondrial and cytoplasmic reductant in excess of that needed to maintain ATP synthesis under normal metabolic circumstances, or in response to abnormal conditions when either ATP synthesis or the cyt pathway is impaired. Recognition of this fact originally served as the basis for the suggestion that the alternative pathway only operated when the activity of the cyt pathway was saturated, the so-called 'energy overflow' hypothesis. Subsequent studies have established that the alternative pathway can compete with the cyt pathway for electrons

from the ubiquinone pool when the cyt pathway is not saturated. This eliminates the overflow hypothesis in its purest form, but not from the standpoint of the alternative pathway helping to regulate mitochondrial electron flow and, as such, maintain mitochondrial redox homeostasis.

One clear outcome of the ability of the alternative pathway to use excess mitochondrial reductant, resulting from either increased input into the ubiquinone pool via the respiratory dehydrogenases or decreased output from the ubiquinone pool via the cyt pathway, is amelioration of the formation of reactive oxygen species (ROS; superoxide, hydrogen peroxide, and hydroxyl radical) that results from over-reduction of the ubiquinone pool. Operation of the alternative pathway has been shown to decrease both the reduction state of the ubiquinone pool in roots and the formation of ROS in plant culture cells. The ability of AOX to decrease mitochondrial ROS formation is the basis of a hypothesis, suggesting that AOX plays a role in plant responses to environmental stresses. In several circumstances where increased mitochondrial ROS levels are predicted, including chilling stress, post-hypoxia-induced reperfusion injury, and reduced Pi availability, AOX gene expression and protein levels are observed to increase markedly.

Similarly, enhanced AOX gene expression and protein formation have been found to accompany oxidative stresses in fungi, including treatment with hydrogen peroxide. A survey of the appearance of the alternative pathway among yeasts found that it was only present in so-called 'Crabtree negative' yeast, which lack the presence of alcoholic fermentation as an option to the cyt pathway consistent with the concept of the alternative pathway serving as a mechanism for eliminating excess reducing equivalents in these organisms.

Glossary

Autophagy All processes in which intracellular material is degraded within the lysosome/vacuole followed by recycling of the macromolecular constituents.

Cytoplasm-to-vacuole targeting A biosynthetic pathway that transports resident hydrolases to the vacuole through a specific autophagy-like process.

Lysosome/vacuole A degradative organelle that compartmentalizes a range of hydrolytic enzymes and maintains a reduced pH.

Macroautophagy An autophagic process involving the formation of a double- or multiple-membrane cytosolic vesicle of non-lysosomal/vacuolar origin.

Microautophagy An autophagic process involving direct uptake of cytosol, inclusions, and organelles at the lysosome/vacuole by protrusion, invagination, or septation of the sequestering organelle membrane.

Mitophagy A selective type of autophagy involving the sequestration and degradation of mitochondria.

Pexophagy A selective type of autophagy involving the sequestration and degradation of peroxisomes.

Autophagy in Mammals

Macroautophagy in Mammals

The phenomenon of macroautophagy has been observed in virtually all eukaryotic cell types. Mammalian hepatic tissues and cell cultures have been extensively studied, where macroautophagy accounts for the majority of macromolecular recycling once it is induced by hormonal or other signals. During starvation-induced macroautophagy, the content of the sequestering vesicles, the autophagosomes, is indistinguishable from the surrounding cytoplasm, and often includes recognizable structures, such as mitochondria and ribosomes, suggesting that the sequestration is nonselective. There also exists evidence for selective sequestration of certain structures, such as peroxisomes and mitochondria, particularly when these organelles are specifically induced to proliferate before the onset of autophagy. Based on morphological and immunocytochemical studies, macroautophagy proceeds through distinct steps of autophagosome formation and maturation (Figure 1).

Formation of autophagosomes

The autophagosomes are distinct from most other intracellular vesicles in that double or multiple delimiting membranes are employed. In addition, formation of these vesicles topologically converts the sequestered cytoplasm to a luminal/extracellular space. Although the membrane source of the sequestering vesicle has been extensively investigated, the origin is still not known, and, in fact, it may be derived from several organelles. The autophagosomal membranes are extremely poor in proteins, indicating that they do not have protein profiles typical of most endomembranes, which also makes it difficult to determine their origin; however, various studies implicate the endoplasmic reticulum, the Golgi complex, and mitochondria as potentially providing lipids. The initial sequestering membrane is termed the 'phagophore', and this expands into an autophagosome by membrane addition.

Maturation of the phagophore

Maturation of phagophores into autophagosomes is thought to occur in a stepwise manner. That is, the autophagosome likely does not form in a single step from a pre-existing membrane, such as a cisterna of the endoplasmic reticulum (ER). Rather, additional phospholipids may be added by vesicular fusion or by direct flow from a source membrane(s). Upon completion, which is marked by closure of the phagophore membrane, the cytosolic vesicle becomes a double-membrane autophagosome. The autophagosomes fuse with lysosomes to acquire degradative enzymes, and the resulting structure is termed an 'autolysosome'. As a result of fusion, the inner autophagosomal membrane is exposed to the lysosome lumen, where it is broken down to allow access of the sequestered cytoplasm to the lysosomal hydrolases. The cytoplasmic cargo is subsequently degraded and recycled for use by the cell; the breakdown products are released into the cytosol through lysosomal membrane permeases. A population of autophagosomes may fuse with endosomes to give rise to 'amphisomes', an intermediate compartment named for its dual role in both macroautophagy and endocytosis. The amphisome ultimately fuses with a lysosome to allow degradation of its cargo.

Regulation of macroautophagy in mammals

The regulatory mechanism of macroautophagy is rather complex. Hormones and metabolites may activate or inhibit autophagy in different tissues. The intracellular signaling pathway has been studied mainly by using reagents that can alter the rates of autophagic protein degradation. It is very likely that the cellular responses to these reagents are pleiotropic. Various proteins have been identified that play a role in regulating macroautophagy, including a phosphatidylinositol 3-kinase (PtdIns3K), heterotrimeric G proteins, protein kinases, and phosphatases. Inhibition of membrane fusion and cytoskeletal functions affect the final stages of cargo delivery. Table 1 lists some of the factors and chemicals that affect macroautophagy.

Figure 1 Macroautophagy in mammals. The initial sequestering membrane is termed the 'phagophore'. Upon closure, the resulting double-membrane cytosolic vesicle is called an 'autophagosome'. The origin of the phagophore or autophagosomal membrane is not known, but may include the endoplasmic reticulum, the Golgi complex, and/or the mitochondria. The autophagosome may fuse with an endosome to form an amphisome. The autophagosome or amphisome ultimately fuses with a lysosome, allowing breakdown of the inner vesicle (in the case of the autophagosome), followed by degradation and recycling of the vesicle contents.

Table 1 Inhibitors of macroautophagy in mammals

Compounds	Effects on autophagy	Mechanism/targets
<i>Physiological effectors</i>		
Amino acids	Decrease	Charged tRNA and surface receptors
Anabolic hormones (insulin, IGF, and EGF)	Decrease	Signaling
Catabolic factors/hormones (cyclic AMP and glucocorticoids)	Increase	Signaling
<i>Pharmacological agents</i>		
Bafilomycin A ₁	Decrease	Vacuolar-ATPase
Chloroquine	Decrease	Lysosomal pH
Cycloheximide	Decrease	Ribosome
Cytochalasin B	Decrease	Microfilaments
Colchicine and vinblastine	Decrease	Microtubules
Lithium	Increase	Inositol monophosphatase
Okadaic acid	Decrease	Serine/threonine protein phosphatases
Rapamycin	Increase	TOR complex
Wortmannin, LY294002, 3-methyladenine	Decrease	Phosphatidylinositol 3-kinase class III

Physiological functions of macroautophagy in mammals

One of the primary functions of macroautophagy is the supply of macromolecules and energy as an adaptive mechanism under starvation conditions in mammals and other organisms. In response to different forms of metabolic stress, such as nutrient deprivation, growth-factor depletion, or hypoxia, activation of autophagy allows degradation of bulk cellular contents to generate free amino acids and other essential blocks of cellular metabolism to be recycled and used for maintaining survival of the organisms. Although occurring at a relatively low level under normal conditions, basal (or constitutive) autophagy is also recognized to play an important role in cellular homeostasis by functioning in the removal of surplus or damaged organelles and in the degradation of misfolded protein aggregates that are too large for the ubiquitin-proteasome system.

Recent studies using gene knockouts in the mouse system provide strong evidence that macroautophagy plays an essential role in the survival of mammals through its functions during both starvation and normal conditions. Mice with knockouts of either *Atg5* or *Atg7*, both encoding essential components of mammalian macroautophagy, die shortly after birth, probably due to their inability to activate macroautophagy in response to the starvation period in neonates. Deletion of FIP200, a component of the ULKs-ATG13-FIP200 complex that is important in the formation of phagophores, leads to embryonic lethality caused by developmental defects in the heart and liver, where autophagy may play a more crucial role due to the high metabolic rate in these organs in late embryogenesis. Tissue-specific knockout of different macroautophagy genes in hepatocytes, neurons, or cardiomyocytes results in the abnormal accumulation of ubiquitinated protein aggregates in inclusion bodies associated with cellular degeneration, suggesting a role for basal macroautophagy in protein quality control in cellular homeostasis and survival.

Microautophagy in Mammals

Microautophagy refers to the direct import of cytoplasmic materials by lysosomal membrane protrusions or invaginations. This process is less well characterized in terms of its mechanisms and its contribution to overall protein degradation. In mammals, lysosomes with appendages or intralysosomal vesicles have been observed *in vivo*. Isolated lysosomes show the ability to uptake and degrade proteins or incorporate electron-dense markers into intralysosomal vesicles. Microautophagy is also induced by environmental cues, such as nutrient deprivation.

Autophagy in Fungi

Macroautophagy in Yeast

Budding yeast as a model for macroautophagy

Ever since the early 1990s, autophagy has been studied using the budding yeast *Saccharomyces cerevisiae* as a model system. Nitrogen or carbon starvation induces the formation of cytoplasmic autophagosomes that have the characteristic double-delimiting membranes. Similar to the findings in mammalian cells, yeast autophagosomal membranes are also protein poor, as revealed

by freeze-fracture electron-microscopy studies. Once formed in the cytoplasm, the outer autophagosomal membrane will fuse with the vacuole (equivalent to the mammalian lysosome) membrane, leaving the inner vesicle, called the 'autophagic body', in the vacuolar lumen. The autophagic bodies are subsequently degraded by vacuolar hydrolases and the degradation products will be released to the cytosol for reuse (Figure 2).

The cytoplasm-to-vacuole targeting pathway and its overlap with macroautophagy

The cytoplasm-to-vacuole targeting (Cvt) pathway was discovered as the biosynthetic targeting pathway of a vacuolar resident enzyme, aminopeptidase I (Ape1). Precursor Ape1 (prApe1) is synthesized in the cytosol. It rapidly assembles into a dodecamer and remains in an oligomerized form during its course of transport into the vacuole (Figure 2). Cleavage of the N-terminal propeptide of prApe1 by vacuolar proteases gives rise to the mature, active form of the protein (mApe1).

Several screens were carried out to identify mutants (*atg*) defective in macroautophagy, the Cvt pathway, and the selective degradation of organelles. Genetic analyses revealed that these mutants overlap. In the case of the Cvt pathway, for example, morphological and biochemical studies confirm that prApe1 is transported to the vacuole using a vesicular mode similar to that of macroautophagy. Precursor Ape1 exists in the cytoplasm as a large structure that can be detected by

electron microscopy. This structure, which consists of multiple prApe1 dodecamers bound to receptor proteins, is called the 'Cvt complex'. Under vegetative growth conditions, the Cvt complex is specifically enwrapped by double-membrane Cvt vesicles. When autophagy is induced, the Cvt complex becomes a preferential cargo of autophagosomes due to the function of the prApe1 receptor. Thus, the Cvt pathway can be regarded as a specific form of autophagy. Another hydrolase, α -mannosidase, is also targeted to the vacuole via the Cvt and autophagy pathways. The parallel studies of the Cvt pathway complement the analysis of autophagy by providing a specific cargo and the opportunity to study selective uptake mechanisms of autophagy.

Molecular mechanism of the Cvt and autophagy pathways in yeast

The molecular machinery of autophagy and the Cvt pathway was identified by cloning the genes that complement the mutants defective in these pathways. Additional components were found by other approaches, including two-hybrid studies. A unified nomenclature was adopted, which uses *ATG* (autophagy-related) to name all the identified genes. Most of the *Atg* proteins are required for both autophagy and the Cvt pathway. Table 2 lists the *Atg* proteins and their proposed roles in these pathways. They can be divided into at least three basic subcategories: (1) *Atg8* and *Atg12* conjugation systems; (2) *Atg9* and its cycling

Figure 2 Cvt pathway and macroautophagy in yeast. (a) The Cvt pathway. Precursor Ape1 (prApe1) forms a dodecamer that assembles into a higher order Cvt complex. Recruitment of the Cvt complex to the PAS leads to the formation of a Cvt vesicle. The completed Cvt vesicle fuses with the vacuolar membrane and releases the inner vesicle (Cvt body) into the vacuole lumen. Breakdown of the Cvt body allows maturation of prApe1 (to mApe1) by removal of a propeptide. (b) Macroautophagy. Under starvation conditions, the PAS is activated by specific signals, resulting in the formation of autophagosomes. The Cvt complex is enclosed along with bulk cytoplasm inside autophagosomes. The inclusion of the Cvt complex is a specific process resulting from the action of receptor and adaptor proteins. Fusion between autophagosomes and the vacuole membrane and the subsequent breakdown of the inner membrane (autophagic body) release the cytoplasmic contents into the vacuole lumen for degradation and recycling or, in the case of the Cvt complex, maturation of precursor aminopeptidase I.

Table 2 Proteins involved in macroautophagy and the Cvt pathway

Protein	Description of function	Cvt ^a	Atg
Atg1	A serine/threonine kinase involved in induction of autophagy; required for Atg9 retrieval from the PAS to peripheral sites; a component of the Atg1-Atg13-Atg17-Atg29-Atg31 complex	–	–
Atg2	Required for Atg9 retrieval from the PAS to peripheral sites	–	–
Atg3	An E2-like enzyme involved in Atg8–PE conjugation	–	–
Atg4	A cysteine protease that cleaves the C-terminal arginine of Atg8 prior to its lipidation and mediates the deconjugation of Atg8–PE	–	–
Atg5	A component of the Atg12–Atg5-Atg16 complex that has an E3-like function in Atg8 lipidation	–	–
Atg6	A component of two PtdIns3K complexes involved in autophagy (complex I) and the Vps pathway (complex II)	–	–
Atg7	An E1-like enzyme involved in the formation of Atg8–PE and Atg12–Atg5 conjugates	–	–
Atg8	A ubiquitin-like protein conjugated to PE; involved in phagophore expansion and usually used as an autophagosome marker	–	–
Atg9	An integral membrane protein that cycles between the PAS and multiple peripheral sites	–	–
Atg10	An E2-like enzyme involved in the formation of Atg12–Atg5 conjugates	–	–
Atg11	A protein involved in cargo recognition and PAS assembly during specific autophagy; mediates Atg9 transport to the PAS during specific autophagy	–	+
Atg12	A ubiquitin-like protein covalently conjugated to Atg5	–	–
Atg13	A component of the Atg1-Atg13-Atg17-Atg29-Atg31 complex; dephosphorylated during starvation conditions	–	–
Atg14	A component of PtdIns3K complex I involved in autophagy	–	–
Atg15	A putative vacuolar lipase required for the lysis of autophagic and Cvt bodies	–	–
Atg16	A component of the Atg12–Atg5-Atg16 complex; determines the localization of the complex and the site of Atg8 lipidation	–	–
Atg17	A scaffold protein essential for PAS assembly during starvation; a component of the Atg1-Atg13-Atg17-Atg29-Atg31 complex that regulates Atg1 kinase activity	+	–
Atg18	A PtdIns(3)phosphate binding protein essential for vesicle formation in autophagy and the Cvt pathway; required for Atg9 retrieval from the PAS to peripheral sites	–	–
Atg19	A cargo receptor in the Cvt pathway; directs the cargo complex to the PAS by interaction with Atg11	–	+
Atg20	A protein with a PX domain that binds to PtdIns(3)phosphate	–	+
Atg21	A PtdIns(3)phosphate binding protein required for the Cvt pathway	–	Partial
Atg22	An amino acid permease on the vacuolar membrane that releases amino acids generated by vacuolar degradation back to the cytosol	+	+
Atg23	A protein partially colocalized with Atg9 and essential for its transport to the PAS	–	Partial
Atg24	A protein with a PX domain that binds to PtdIns(3)phosphate	–	+
Atg25	Not identified in <i>Sacharomyces cerevisiae</i> ; required for pexophagy in <i>Hansenula polymorpha</i>	N.A.	N.A.
Atg26	A protein with a GRAM domain required for pexophagy in <i>Pichia pastoris</i> , but not in <i>S. cerevisiae</i>	+	+
Atg27	An integral membrane protein partially colocalized with Atg9 and essential for its transport to the PAS	–	Partial
Atg28	A coiled-coil protein required for pexophagy in <i>P. pastoris</i> ; not identified in <i>S. cerevisiae</i>	N.A.	N.A.

system; and (3) the PtdIns3K complex and a series of phosphatidylinositol-binding proteins. The molecular mechanism for the Cvt pathway and macroautophagy is briefly outlined below.

Phagophore assembly site and de novo vesicle formation

In vivo fluorescence microscopy studies have colocalized the autophagosomal membrane marker protein Atg8 with several other Atg proteins at a perivacuolar site. This site is physiologically functional and plays a pivotal role in autophagosome formation; therefore, it has been termed the phagophore assembly site (PAS). Localized on the PAS are two conjugates, Atg12 covalently linked to Atg5, and Atg8 covalently attached to phosphatidylethanolamine (Atg8–PE). These conjugates are both essential in the generation of autophagosomes and Cvt vesicles. Formation of the Atg12–Atg5 and Atg8–PE conjugates

involves ubiquitin-like cascades. Recruitment of Atg12–Atg5 and Atg8 to the PAS depends on the function of the transmembrane protein Atg9 and the autophagy-specific PtdIns3K complex (there are two PtdIns3K complexes in yeast), underlying the key role of specific lipids in autophagosome formation. Atg9 cycles between the PAS and multiple peripheral sites, which may represent the donor membranes source(s) that allow expansion of the phagophore.

Regulation of autophagy

The Cvt pathway operates under vegetative conditions, whereas autophagy is induced by starvation. Atg1 is localized at the PAS and is important in signaling Cvt vesicle or autophagosome formation, possibly via its differential association with other proteins such as Atg11 and Atg13. In particular, the

Atg1-Atg13 interaction is regulated by the target of rapamycin (TOR) kinase. Inhibition of TOR activity results in the induction of autophagy. TOR also regulates autophagy at the transcriptional level. Besides TOR, there are other signaling pathways involved in autophagy regulation such as the Ras/cyclic adenosine monophosphate (Ras/cAMP)-dependent protein kinase A (PKA) pathway.

Mechanism for cargo selection in the Cvt pathway and autophagy

The Cvt complex is selectively sequestered by Cvt vesicles or autophagosomes. Atg19, a structural component of the Cvt complex, acts as a receptor and mediates the recruitment of the oligomerized prApe1 cargo and its recognition by the PAS through successive protein-protein interactions with Atg11 and Atg8. This may provide a prototype for other selective autophagic targeting pathways.

Fusion and breakdown

The fusion between the Cvt vesicles or autophagosomes and the vacuole membrane is similar to vacuole homotypic fusion and requires docking/tethering factors in addition to SNARE and Rab proteins. Breakdown of the inner vesicles requires the action of specific components such as the putative Atg15 lipase in addition to other vacuolar hydrolases. Free amino acids generated by vacuolar protein degradation are recycled into the cytosol via vacuolar permeases such as Atg22.

Microautophagy and Selective Organelle Degradation in Yeasts

Nonselective microautophagy

The morphological features of microautophagy have been observed in yeasts. Microautophagic vacuole invagination was also reconstituted *in vitro*. Interestingly, the molecular components of macroautophagy, the Atg proteins, were implicated to function at least partly in microautophagy as well, although in the case of nonselective microautophagy this may be indirect; microautophagy may function in part to maintain vacuole-membrane homeostasis by removing membrane following fusion of vesicles, including those of macroautophagy, with the vacuole-limiting membrane.

Pexophagy: Selective autophagy of peroxisomes in methylotrophic yeasts

Selective degradation of peroxisomes by autophagic mechanisms has been best demonstrated in methylotrophic yeasts. Peroxisomes are necessary for utilizing methanol and are induced when methanol is the sole carbon source. Upon shift of culture medium to preferred carbon sources, superfluous peroxisomes are targeted to the vacuole via either a macro- or microautophagic mode, depending on nutrient conditions. The selective degradation of peroxisomes is termed 'pexophagy'. The proteins involved in selective macroautophagy of peroxisomes (macropexophagy), and even those required for selective microautophagy of peroxisomes (micropexophagy), are generally found to be homologous to the Atg proteins. This latter finding suggests that macroautophagy and selective microautophagy may be more closely related at the molecular level than they appear to be morphologically.

Mitophagy: Selective degradation of mitochondria via autophagy

Mitochondria are critical for supplying energy in eukaryotic cells, but they also generate reactive oxygen species during catabolism, which can potentially harm cells. Mitophagy plays an important role in the elimination of damaged or excess mitochondria, depending on the energy requirement. In *S. cerevisiae*, mitophagy can be induced by nitrogen starvation or treatment with the TOR inhibitor rapamycin after pre-culturing in nonfermentable media, which induce mitochondrial proliferation. The autophagy machinery is essential for mitophagy. In addition to the known ATG genes, genetic screening has identified additional genes required specifically for mitophagy (e.g., ATG32 and ATG33). Further analyses will be needed to characterize the specific roles of the corresponding gene products in mitophagy.

Autophagy, from Yeast to Mammals

Most of the Atg proteins are conserved in higher eukaryotes, suggesting that the mechanism for autophagy is similar in yeasts and mammals. Future studies with mammalian cells may further benefit from the molecular model provided by yeast systems. However, there are also some Atg proteins that are unique to higher eukaryotes, perhaps reflecting the increased roles for macroautophagy in these organisms. For example, abnormalities in autophagy are connected with various human pathophysiologicals, such as neurodegeneration and certain types of cancer. The importance of autophagy in developmental or pathological macromolecular turnover in higher eukaryotes promises to be an exciting area of future research due to its potential therapeutic implications.

Glossary

B₁₂ A complex organometallic cofactor, also called cobalamin, that is used by the enzymes that catalyze group transfer or radical-mediated rearrangement reactions.

Cofactor A compound that is noncovalently associated with an enzyme and is required for the catalytic activity.

Radical A species that contains an unpaired electron.

The Cobalamin Cofactor

The central feature of the cobalamin cofactor (**Figure 1(a)**) is a cobalt atom with octahedral geometry, which is centered in the corrin macrocycle by coordination to pyrrole nitrogens from the corrin in the four equatorial coordination positions of the metal ion. A nitrogen atom that is donated by a dimethylbenzimidazole moiety, which in turn is ligated to the corrin ring, coordinates the cobalt from the lower axial position. In some eubacteria and Archaea, the dimethylbenzimidazole substituent of the cobalamin is replaced by other compounds (e.g., *p*-cresol); such cofactors are referred to as corrinoids. The macrocycle is further adorned by methyl, acetamide, and propionamide side chains. The upper axial position of the cobalt ion is occupied by an alkyl substituent specific to the type of reaction catalyzed by the protein.

The upper face of the cobalamin is where the chemistry takes place in all cobalamin-dependent enzymes. The chemical versatility of cobalamin and corrinoids lies in the carbon–cobalt bond of the cofactor, which is susceptible to cleavage by heterolytic or homolytic pathways (see **Figure 1(b)**). The upper coordination position of the cobalamin, in the enzymes that catalyze methyl group transfer, is transiently occupied by a methyl group en route from a donor molecule to an acceptor molecule. In these enzymes, the cobalamin serves both as a nucleophile, accepting the methyl group from the donor, and as a leaving group, donating the methyl group to an acceptor molecule. By contrast, enzymes that catalyze radical-mediated transformations require that the cobalamin has 5'-deoxyadenosine coordinated to the cobalt on the upper face of the corrin. In these enzymes, the organometallic bond between the 5'-methylene of the deoxyadenosyl moiety and the cobalt is severed homolytically to generate a 5'-deoxyadenosyl radical, which initiates the radical cascades that lead to the formation of product.

The identity of the ligand that occupies the lower axial coordination position of protein-bound cobalamin may differ significantly from that in solution. In some proteins, in addition to the network of interactions with the side chains of the corrin, the imidazole side chain of a histidine residue substitutes for the dimethylbenzimidazole of the cofactor and donates a nitrogen ligand to the cobalt. This latter form of binding is referred to as a base-off binding mode. Most of the proteins that bind the cobalamin in the base-off mode also contain a DxHxxG sequence that contains the histidine residue that donates the lower axial imidazole ligand. In other proteins, binding of cobalamin to the protein backbone is accomplished by extensive interactions with the corrin and its side chains, and the dimethylbenzimidazole remains coordinated to the cobalt atom. This is referred to as base-on binding of the cofactor.

The cobalamin cofactor can exist in three oxidation states, and each form of the cobalamin exhibits distinct ultraviolet (UV)–visible spectra that allow one to follow the course of the catalytic cycle. For instance, the cobalt in alkyl cobalamins, such as adenosylcobalamin or methylcobalamin, is in the +3 oxidation state (formally, the alkyl ligand is considered to be the anion R[−]). Homolysis of the cobalamin to generate a deoxyadenosyl radical is accompanied by the formation of a reduced cobalamin, cob(II)alamin, in which the cobalt is in the +2 oxidation state, and reformation of the C–Co bond of the cofactor oxidizes the cobalt to the +3 state. Therefore, adenosylcobalamin-dependent proteins cycle between the +3 and +2 oxidation states during the course of the catalytic cycle. By contrast, upon nucleophilic displacement of methyl group from the cobalamin during group transfer chemistry, the cobalamin cycles between the +3 oxidation state in the methylcobalamin form and the +1 state upon loss of the alkyl group. Remethylation of the cobalamin reoxidizes the cobalamin to the +3 oxidation state.

Figure 1 Structure and reactivity of alkylcobalamins: (a) the upper coordination position of cobalamin can be occupied by 5'-deoxyadenosine or a methyl group; (b) homolysis of the C–Co bond in adenosylcobalamin-dependent enzymes generates a 5'-deoxyadenosyl radical and cob(II)alamin. By comparison, the cofactor is transiently methylated in enzymes that catalyze group transfer reactions.

In this article, we summarize the reactions that are catalyzed by cobalamin-requiring enzymes, first highlighting the reactions in which cobalamin serves as a source of the highly reactive 5'-deoxyadenosyl radical and then discussing the reactions that involve methyl transfer chemistry.

Reactions Catalyzed by Cobalamin-Dependent Enzymes

Radical-Mediated Rearrangement Reactions

The enzymes that catalyze radical-mediated transformation exploit the inherent weakness of the carbon–cobalt bond of adenosylcobalamin (bond dissociation energy $\sim 30 \text{ kcal mol}^{-1}$) to form the highly reactive 5'-deoxyadenosyl radical. Binding of the cobalamin to these enzymes accelerates the rate of homolysis of the C–Co bond $\geq 10^{12}$ -fold. Homolysis of the carbon–cobalt bond is triggered by the presence of the substrate or by an allosteric effector. Presumably, the binding energy derived from substrate/effector–enzyme interactions is essential to elicit the conformational changes that are required to facilitate homolysis of the relatively weak organometallic bond. The 5'-deoxyadenosyl radical is a primary radical and readily abstracts a hydrogen atom from the substrate or from a residue on the protein. Therefore, a hallmark of catalysis by the enzymes in this group is formation of radical intermediates. **Figure 2** shows the general catalytic cycles for these enzymes.

Adenosylcobalamin-dependent enzymes can be divided into four groups based on the details of the catalytic transformations (**Table 1**). The reactions catalyzed by enzymes in each group are discussed next.

Migration and Elimination Reactions

The enzymes in this group participate in the fermentation of short-chain organic compounds such as ethanolamine, glycerol, 1,2-propanediol, and 1,2-ethanediol. The reactions catalyzed by these enzymes are formally the interchange of a

hydrogen atom on one carbon with a group X ($=\text{OH}$ or NH_3) at the adjacent position. The catalytic mechanism of these enzymes is quite similar to the mechanism of the carbon skeleton mutase enzymes discussed later. These two groups, in fact, differ only in that the mutases retain the rearranged substituent.

The catalytic mechanisms of ethanolamine ammonia-lyase and diol dehydratase have been studied extensively and a generalized mechanism for these enzymes is shown in **Figure 2(a)**. As with all cobalamin-dependent enzymes, the carbon–cobalt bond of the cofactor is homolyzed to generate 5'-deoxyadenosyl radical and cob(II)alamin in the first step of the catalytic reaction. The deoxyadenosyl radical abstracts a hydrogen atom from the substrate (S–H) to generate a substrate-like radical ($\text{S}\cdot$) $\sim 9\text{--}12 \text{ \AA}$ away from the cob(II)alamin. The rearrangement of $\text{S}\cdot$ to a product-like radical ($\text{P}\cdot$) followed by return of a hydrogen atom from the 5'-deoxyadenosine results in the formation of the enol form of the product (P–H). The deoxyadenosyl radical recombines with cob(II)alamin to regenerate adenosylcobalamin. The initial *gem*-diol or *gem*-amino alcohol that is formed in the course of these transformations subsequently eliminates water or ammonia, respectively, to generate the corresponding aldehydes.

Diol and glycerol dehydratases have the best-characterized structures in this group. Few sequence similarities exist between the diol and glycerol dehydratases and ethanolamine ammonia-lyase, despite the similarities in the reactions that they catalyze. Nevertheless, members of these groups of enzymes appear to retain coordination of the cobalamin to dimethylbenzimidazole.

Diol dehydratase and glycerol dehydratase are rapidly inactivated in the course of their catalytic cycle by side reactions that lead the formation of tightly bound inactive cofactor at the active site of these enzymes. The gene clusters that code for the structural genes for these proteins also contain open reading frames whose products have been shown to catalyze the adenosine triphosphate (ATP)- and Mg^{2+} -dependent exchange of inactive cofactor with cofactor from solution. The generality of the reactivation mechanism remains to be determined.

Figure 2 Generalized reaction cycles for enzymes that catalyze radical-mediated rearrangements. (a) The catalytic cycles for enzymes that catalyze rearrangements and eliminations, carbon skeleton rearrangements, and PLP-dependent aminomutase reactions. The structures on the right are examples of the intermediates that would be expected in the conversion of ethanolamine acetaldehyde and ammonia by ethanolamine ammonia-lyase. (b) The catalytic cycle of ribonucleotide triphosphate reductase differs from the cycle in (a) in that the 5'-deoxyadenosyl radical abstracts a hydrogen atom from an active site cysteine thiol to generate a thiyl radical that subsequently generates a substrate-based radical species. The structures on the right show some of the reaction intermediates that form in the course of conversion of ATP to dATP.

Carbon Skeleton Rearrangement Reactions

As with the enzymes that catalyze rearrangement and elimination, the enzymes in this group catalyze the interchange of a hydrogen atom on one carbon atom with an alkyl group on the adjacent carbon atom (see Table 1). The reactions catalyzed by these enzymes differ from the others in several respects. First, the migrating alkyl group is not eliminated from the product. Second, the mutase reactions are reversible. Two significant structural differences have also been noted between these enzymes. First, spectroscopic and structural studies have shown that cobalamin binds in the base-off conformation and that the histidine residue that donates the imidazole ligand is conserved in the members of the group. Second, the substrate-based radicals that are formed in the course of the reaction reside 6 Å away from the cob(II)alamin. However, despite these differences, the 5'-deoxyadenosyl radical is involved in generating a substrate-based radical and the catalytic cycle of these enzymes resembles that of the enzymes that catalyze rearrangement and elimination reactions (see Figure 2(a)).

Pyridoxal 5'-Phosphate-Dependent Aminomutase Reactions

Pyridoxal 5'-phosphate (PLP)-dependent aminomutases catalyze the interchange of a hydrogen atom with an amino group on the adjacent carbon atom. These enzymes (see Table 1) have been purified from several strict anaerobes that catabolize lysine or ornithine to organic acids and ammonia. The salient features of the generic aminomutase mechanism are the formation of a Schiff base linkage between the substrate and PLP and the use of 5'-deoxyadenosyl radical to initiate catalysis. In these enzymes, the PLP may assist in the intramolecular migration of the amino group. In addition to the presence of PLP, these enzymes differ from the enzymes that catalyze migration and elimination reactions in that aminomutases catalyze a reversible interchange of a hydrogen atom with the amino group on the adjacent carbon atom and the cofactor binds in a base-off configuration. Despite these differences, the catalytic cycle shown in Figure 2(a) applies to these enzymes as well.

Table 1 Adenosylcobalamin-dependent radical-mediated transformations

Group 1	Rearrangement/elimination reactions	
	Diol dehydratase	1,2-propanediol → propionaldehyde + water
		Ethylene glycol → acetaldehyde + water
	Glycerol dehydratase	Glycerol → 3-hydroxypropionaldehyde
	Ethanolamine ammonialyase	Ethanolamine → acetaldehyde + ammonia
Group 2	Carbon skeleton mutases	
	Methylmalonyl-CoA mutase	(2R)-methylmalonyl-CoA ⇌ succinyl-CoA
	Isobutyryl-CoA mutase	Isobutyryl-CoA ⇌ <i>n</i> -butyryl-CoA
	Glutamate mutase	<i>S</i> -glutamate ⇌ (2 <i>S</i> ,3 <i>S</i>)-3-methylaspartate
	2-Methyleneglutarate mutase	2-methyleneglutarate ⇌ (R)-3-methylitaconate
Group 3	PLP-dependent aminomutases	
	Lysine 5,6-aminomutase	D-lysine ⇌ 2,5-diaminohexanoic acid
		L-β-lysine ⇌ 3,5-diaminohexanoic acid
	D-ornithine 4,5-aminomutase	D-ornithine ⇌ (2 <i>R</i> ,4 <i>S</i>)-diaminopentanoate
Group 4	Ribonucleotide reduction	
	Ribonucleotide triphosphate reductase	Ribonucleotide triphosphate → deoxyribonucleotide triphosphate

Ribonucleotide Triphosphate Reductase Reaction

Ribonucleotide reductases catalyze the conversion of nucleotides to deoxynucleotides in all organisms. The prominent role of these enzymes in nucleotide metabolism has made them attractive targets of antiviral and antitumor therapies. Ribonucleotide reductase can synthesize all four DNA bases from the corresponding nucleosides; however, the activity of the enzymes from all sources is allosterically regulated by the ratio of the deoxyribonucleotides and nucleotides. Four classes of reductases have been described. Although the overall reactions catalyzed by all of these enzymes are identical, they differ in two respects. First, some use nucleoside diphosphates as substrates, whereas others prefer nucleotide triphosphates. Second, these enzymes differ in the source of the species that initiates the radical turnover cascade. In fact, ribonucleotide reductases have been categorized into four classes based on the free-radical initiators. Only one of these, the class II ribonucleotide triphosphate reductase, is adenosylcobalamin dependent. However, the catalytic transformations that ensue following the formation of the substrate radical are remarkably similar. The ribonucleotide triphosphate-specific enzyme from *Lactobacillus leichmannii* is the best-characterized example of adenosylcobalamin-dependent reductases.

The mechanistic details of the ribonucleotide reduction differ significantly from the paradigms that have been discussed in

the previous sections for the group migration and elimination, aminomutase, and carbon skeleton mutase enzymes. First, ribonucleotide reductases contain a pair of active-site cysteine residues that are oxidized in the course of the reaction and must undergo reduction between each catalytic cycle. Second, a cysteine on the protein forms a thiyl radical that is directly involved in the reaction. **Figure 2(b)** shows a general catalytic cycle for the adenosylcobalamin-dependent ribonucleotide reductase, highlighting the differences between this enzyme and other radical-mediated rearrangement reactions. The carbon–cobalt bond of the cofactor is homolyzed by the protein in the presence of allosteric effector; the resulting 5'-deoxyadenosyl radical abstracts a hydrogen atom from an active-site cysteine residue to generate a thiyl radical, which in turn abstracts a hydrogen atom from C3' of the substrate. In the course of reduction of the substrate to the product, a pair of active-site thiols is oxidized and the active-site thiyl radical is reformed. Reformation of the cofactor and reduction of the active-site thiols prepare the active site for subsequent turnover.

Methyl Transfer Reactions

Enzymes that catalyze cobalamin-dependent methyl transfer reactions use the potential for heterolytic cleavage of the carbon–cobalt bond of the cofactor (see **Figure 1(b)**). The cofactor

Figure 3 Diversity of methyl group donors and acceptors in cobalamin-dependent methyltransferase enzymes.

Figure 4 Catalytic cycle of cobalamin-dependent methionine synthase. The dashed box shows the reactivation of the oxidized cofactor by reductive methylation.

in these enzymes serves both as a nucleophile and as a leaving group, undergoing transient methylation in the course of the reaction. Although the identities of the donor and acceptor molecules vary among the family of cobalamin-dependent methyl transferase enzymes (**Figure 3**), the overall catalytic cycles of these enzymes are similar. In this section, we consider methionine synthase as a prototype of the cobalamin-dependent methyltransferases, highlighting the similarities and differences among the members of the methyl transferase family of enzymes.

Cobalamin-Dependent Methionine Synthase

Cobalamin-dependent methionine synthase is found in mammals and in *Caenorhabditis elegans*, but not in insects or in plants, which neither produce nor transport cobalamin. It is also found in many prokaryotes, including *Escherichia coli*, but not in Archaea. The enzyme catalyzes the transfer of a methyl group from the tertiary amine methyltetrahydrofolate to the thiol of homocysteine, and the cobalamin cofactor serves as an intermediary in the methyl transfer. A catalytic cycle for methionine synthase is shown in **Figure 4**.

Methionine synthase is a large monomeric protein (1227 amino acid residues in the enzyme from *E. coli*) containing four discrete modules. The N-terminal module binds and activates homocysteine; the thiol of homocysteine coordinates to a catalytically essential zinc metal ion in this module. The next module in the sequence binds and activates methyltetrahydrofolate. Each of these substrate-binding modules communicates with the third module in the sequence, the B₁₂-binding

module, to transfer methyl groups to and from the base-off cofactor. The C-terminal module is required for the activation of methionine synthase when the cob(I)alamin cofactor becomes oxidized during turnover (1 in 2000 turnovers results in oxidation *in vitro*). Activation of the inactive cob(II)alamin form of the cofactor requires both a methyl donor and an electron donor. The methyl donor is S-adenosyl-methionine. In *E. coli* the electron donor is reduced flavodoxin, and in mammals it is methionine synthase reductase, a protein containing a domain with homology to flavodoxin. To allow methyl transfer during reductive activation, the C-terminal domain must also access the cobalamin; a structure of a fragment of methionine synthase in this conformation has recently been determined.

Methyl Transferases Involved in Methanogenesis and Acetogenesis

Although cobalamin-dependent methionine synthase is the only B₁₂-dependent methyl transferase in eubacteria and eukaryotes, a large number of enzymes catalyzing similar methyl transfers that employ corrinoid cofactors have been identified in Archaea and acetogenic eubacteria. The diversity in the methyl group donor-acceptor pairs is illustrated in **Figure 3**. In general, in methanogens, corrinoid-dependent enzymes are involved in the formation of methylcoenzyme M, the methyl thioether that provides the methyl group destined to form methane in methanogenesis. The methyl donors in these reactions include methyltetrahydromethanopterin, which is

chemically similar to methyltetrahydrofolate. The methyl group of methyltetrahydromethanopterin is formed by the reduction of carbon dioxide using reducing equivalents derived from molecular hydrogen. Some methanogens can also use simple compounds such as methylamines, methanol, or methylsulfides as the source of methyl groups for methanogenesis. In contrast to cobalamin-dependent methionine synthase, in which a single protein catalyzes methyl transfer from methyltetrahydrofolate to cobalamin and from methylcobalamin to homocysteine, most of these methanogenic methyl transferase reactions require three separate proteins, a corrinoid-containing protein, a methyltransferase that transfers methyl groups from the donor molecule to the corrinoid protein, and a second methyltransferase that transfers methyl groups from the methylcorrinoid protein to the acceptor.

Eubacterial acetogenesis also involves corrinoid-dependent methyl transferases. In these organisms, carbon dioxide and hydrogen are used to generate acetyl coenzyme A (CoA). The methyl group of acetyl CoA is generated by reduction of carbon dioxide using reducing equivalents from molecular hydrogen, as in methanogens, and is transferred to a corrinoid cofactor that serves as the direct methyl donor to the enzyme responsible for the synthesis of acetyl CoA from a methyl group and carbon dioxide. Additional acetogenic substrates include vanillate, veratrol, and halogenated aryl or alkene compounds. The precise nature of the chemistry that is promoted by cobalamin with the last substrates remains to be elucidated.

Glossary

Antibody A protein that is produced in response to immune challenge and binds specifically to a particular antigen.

Antigen A molecule that specifically binds an antibody.

Avidity The sum of the binding strengths of all points of interaction between an antigen and an immunoglobulin.

Humoral immune response The antibody-mediated response to a specific antigen.

Immunoglobulin A protein complex with a characteristic structure of heavy and light chains.

Isotype A class of immunoglobulin as determined by the constant region.

Somatic hypermutation The process by which mutations are introduced into the heavy- and light-chain genes.

B-cell functions in the immune system are dependent on their ability to recognize foreign antigens and to discriminate between foreign antigens and self-antigens. The complex of proteins responsible for the identification of foreign antigens is the B-cell antigen receptor (BCR) complex. Signals originating with the BCR can lead to a variety of cell fates, depending on the developmental stage of the B cell and the concentration and avidity of the antigen. B-cell precursors in the bone marrow require BCR signals for survival. Once a competent signaling complex is formed, the BCR is tested to ensure that it does not react with self-antigens. If the BCR is ligated by self-antigens, it must either change its specificity or undergo cell death. Later in B-cell development, basal BCR signaling is required for the survival and homeostatic maintenance of the B-cell pool. BCR stimulation of mature B cells initiates an immune response, characterized by the proliferation and differentiation of B cells into either antibody-producing plasma cells or memory B cells. Hence, a competent BCR that recognizes foreign antigens and not self-antigens is critical for the development and maintenance of B cells and for the initiation of humoral immune responses.

Structure of the BCR

The BCR complex contains a membrane-bound immunoglobulin (mIg). mIg can be one of five isotypes: IgM, IgD, IgA, IgG, or IgE. The isotype of mIg expressed on a given B cell varies with the stage of development and activation. Immature and transitional B cells express mIgM, whereas mature resting B cells express mostly mIgD and some mIgM. Cells that have been activated undergo a process called 'isotype class-switching' and may then express mIgG, mIgA, or mIgE in addition to soluble IgG, IgA, or IgE. The process of isotype class-switching results in the activation of other hematopoietic cells. Each molecule of mIgM contains two heavy-chain (H) and two light-chain (L) proteins, that is H2L2 (Figure 1). Disulfide bonds link the heavy chains to one another and each heavy chain is disulfide bonded to a light chain. At the membrane proximal end of the heavy chain is a transmembrane domain followed by a short intracellular domain. mIgM and mIgD contain only three intracellular residues that anchor the

protein in the membrane. Other classes of mIg contain slightly longer intracellular domains and appear to mediate functions only present in B cells that express mIgG, mIgA, or mIgE.

The short intracellular domains of mIgM and mIgD alone cannot generate a signal; mIg-associated accessory proteins fulfill this function. There are two such accessory molecules, Ig α (also called CD79a) and Ig β (CD79b). The interaction between mIg and Ig α /Ig β depends on the transmembrane domains of each protein. The transmembrane domains of mIg, Ig α , and Ig β are α -helices and contain both polar and nonpolar regions. The polar regions are critical for protein-protein interactions among the BCR components. mIg contains polar residues on both sides of the α -helix. One side is conserved among all Ig isotypes and the other side is isotype specific. The residues that are isotype specific allow for oligomerization of the BCR complex. The degree of oligomerization varies with each Ig isotype. The side of the molecule that is conserved among all isotypes participates in the association between mIg and Ig α /Ig β .

Like mIg, the transmembrane domain of Ig α contains polar residues on both sides of the α -helix. By contrast, Ig β contains polar residues on only one side of the α -helix. Thus, a favored model for the structure of the BCR complex is that Ig α bridges mIg and Ig β (Figure 1). According to this model, when the BCR complex is assembled, the polar residues within the transmembrane domains are masked by protein-protein interactions. This is essential for the surface expression and stability of the BCR.

BCR Diversity

In order to contribute to protective immunity to a range of pathogens, B cells must be able to recognize a vast array of antigens. The diversity of the Ig repertoire is accomplished using three factors: combinatorial diversity, junctional diversity, and somatic hypermutation. Combinatorial diversity occurs through the recombination of sets of heavy- and light-chain gene segments. Three gene segments, variable (VH), diversity (DH), and joining (JH), recombine to form the variable region of the heavy chain. There are many VH gene segments, DH gene segments, and JH gene segments. Thus, sets of

Figure 1 The structure of the BCR. The BCR consists of two heavy chains disulfide bonded to one another. Each heavy chain is disulfide bonded to a light chain. Ig α and Ig β are also disulfide linked. mIg and Ig α /Ig β are noncovalently coupled. Also shown is the ITAM motif on Ig β ; Ig α and Ig β each have one ITAM motif.

different segments recombine to form a range of different VDJH genes. The light chain undergoes a similar process of recombination. To generate the light chain, two gene loci, κ and λ , undergo recombination. Here, VL and JL gene segments recombine and result in VJL. The combination of heavy-chain rearrangement and light-chain rearrangement results in substantial BCR diversity.

Junctional diversity also arises from the recombination of the gene segments. When a VH gene segment recombines, nucleotides may be added or subtracted. This results in the addition or loss of amino acids or a shift in the reading frame of the new gene. The third mechanism by which diversity is introduced to the BCR repertoire is through somatic hypermutation (discussed later).

BCR Signaling

Ligation of the BCR complex triggers a series of events that ultimately affects the fate of the cell. A B cell stimulated through the antigen receptor may proliferate, differentiate, or undergo apoptosis. B cells are also very efficient antigen-presenting cells. BCR signaling is essential for antigen internalization and processing after the BCR binds and captures antigen.

Antibody–Antigen Interactions

Antigens interact with the variable regions of mIg. Within the variable region, there are framework regions interspersed with three hypervariable regions, the areas that contain the most variability. The framework regions, folded as β -sheets, provide much of the antibody structure. The hypervariable regions are

located on one edge of the β -sheets. To provide even greater repertoire diversity, the hypervariable regions of the heavy and light chain are within close proximity to one another and together create the antigen-binding site. Haptens and other small antigens bind the antibody in the grooves between the hypervariable regions of the heavy and light chains. Interactions between the BCR and larger antigens may extend into the framework region. The interactions between the antibodies and antigens are noncovalent in nature. These interactions may consist of electrostatic interactions, van der Waals interactions, hydrophobic interactions, and hydrogen bonding.

Early Signaling Events

Ig α and Ig β each contains tyrosine residues that are phosphorylated following BCR engagement. Two of the tyrosine phosphorylation sites on Ig α and Ig β are located within immunoreceptor tyrosine-based activated motifs (ITAMs) (Figure 1). These regions contain six conserved residues in the specific configuration, D/ExxxxxxD/ExYxxLxxxxxxYxxL/I. The spacing between the tyrosine residues in the ITAM results in these residues being positioned on the same side of an α -helix, facilitating the interactions with downstream SH2-domain-containing signaling molecules. (SH2 domains are motifs that bind phosphotyrosine and the surrounding residues.)

In addition to the ITAM tyrosine residues, Ig α and Ig β contain other residues that become phosphorylated. Non-ITAM tyrosine residues may also recruit SH2-domain-containing signaling proteins. Serine/threonine phosphorylation of Ig α may negatively regulate phosphorylation of the ITAM tyrosine residues and, therefore, may negatively regulate downstream signaling.

Three families of protein tyrosine kinases (PTKs) play key roles in the initiation of BCR signaling ([Figure 2](#)). These kinases are Src-family PTKs, such as Lyn; the Syk/ZAP-70 family PTKs, such as Syk; and the Tec-family PTKs, such as Btk. Following BCR ligation, Lyn becomes activated and phosphorylates the ITAM tyrosines. The phosphorylated ITAM becomes the docking sites for Syk, which has two tandem SH2 domains. The binding of the SH2 domains of Syk to the phospho-ITAM contributes to its activation. Syk can also become activated in the absence of Src-family PTKs. A small amount of Syk is constitutively associated with the BCR complex. Cross-linking the BCR leads to the clustering of Syk, which then may transautophosphorylate and become activated. Activation of Syk and Lyn, then, leads to the activation of Btk. The combination of Syk, Lyn, and Btk activity is necessary for optimal signaling through the BCR.

Downstream Signaling Events

The activation of Syk-, Src-, and Tec-family PTKs trigger a number of downstream signaling pathways (Figure 2). For example, phosphatidylinositol 3'-kinase (PI3-K) and phospholipase C- γ 2 (PLC- γ 2) are two enzymes that generate second messengers in BCR signaling. PI3-K is a lipid kinase important for the recruitment and activation of PH-domain-containing proteins. (PH domains are motifs that bind phospholipids.)

Figure 2 BCR-mediated signaling events. Following antigen binding to the BCR complex, tyrosine residues on Igα and Igβ become phosphorylated and bound by the tandem SH2 domains of the Syk. Lyn is also activated. The activation of these two PTKs trigger many downstream signaling cascades, including the activation of PI3-K and PLC-γ2.

PLC-γ2 generates inositol-1,4,5-triphosphate (IP₃) and diacylglycerol (DAG), second messengers critical for calcium influx and protein kinase C activation. The activation of these signaling pathways, along with many other pathways, leads to gene transcription and cell-fate decisions, such as proliferation, apoptosis, or differentiation.

In addition to gene transcription, BCR signaling is also critical for antigen internalization and processing. When the BCR binds an antigen, the BCR complex is internalized. The antigen is then processed and presented on the cell surface in order to activate antigen-specific T cells.

The BCR and the Immune Response

When antigen and other immune cells activate a B cell, a complex series of events takes place that can result in proliferation, somatic hypermutation, isotype class-switching, and

differentiation. The BCR on mature naïve B cells may be able to recognize more than one antigen. This multispecific nature of the BCR results in relatively low affinity to any specific antigen. Somatic hypermutation is a process by which high-affinity BCRs are generated. Under some conditions following BCR ligation, a somatic hypermutation program is induced. During somatic hypermutation, mutations are introduced into the V segment of the heavy- and light-chain genes. After somatic hypermutation, B cells expressing BCRs with high affinity are selected for further expansion. In this way, the immune system creates B cells that have produced high-affinity antibodies tailor-made for specific pathogens.

The other major changes in the BCR following B-cell activation include isotype class-switching. The genomic organization of mIg is the recombined variable region followed by the constant genes of μ , δ , $\gamma 3$, $\gamma 1$, $\gamma 2b$, $\gamma 2a$, and α in mice and μ , δ , $\gamma 3$, $\gamma 1$, $\alpha 1$, $\gamma 2$, $\gamma 4$, and $\alpha 2$ in humans. Following the activation of the B cell through certain key receptors such as CD40, DNA recombination can occur so that the VH joins a CH segment of another isotype. This process is a guided repetitive DNA sequence preceding each constant domain known as a 'switch region'. The precise mechanism of class-switching is unknown, but probably involves DNA recombination between homologous repeats in the switch regions of different constant genes.

The result of somatic hypermutation and class-switching is the generation of highly specific antibodies of an isotype that generates an effective immune response. In particular, the constant regions of the antibody bind specific receptors on other immune cells. For example, the constant region of IgGγ1 and IgGγ3 bind Fcγ receptors on macrophages and neutrophils leading to phagocytosis of the antigen, whereas the constant region of IgE binds Fc receptors on mast cells and basophils leading to the secretion of inflammatory agents.

Membrane-bound forms of IgG, IgA, and IgE may function differently than mIgM and mIgD. Cross-linking mIgG leads to the proliferation and antibody secretion of mIgG-expressing B cells. Although mIgG and mIgM activate similar downstream signaling pathways, mIgG cross-linking triggers a much more robust response than does mIgM cross-linking. This may be due to the fact that mIgG is resistant to downregulation by certain B-cell coreceptors, such as CD22. The mechanism for this resistance may be related to differences in the intracellular domains between mIgM and mIgG.

Summary

The BCR complex is a critical component of the humoral immune response. The BCR repertoire must be diverse enough to recognize an incredible number of foreign antigens, but must also avoid targeting self-antigens. Ligation of the BCR triggers a complex series of events that include the activation of PTKs, the phosphorylation of Igα and Igβ, and the initiation of multiple signaling cascades. These signaling pathways lead to cell-fate decisions, antigen presentation, and an immune response.

Glossary

Apoptosis A physiological form of cell death with a characteristic morphology whose mechanism is shared by metazoans.

Bcl2 family proteins Proteins that have a structural similarity to the apoptosis inhibitory protein Bcl2.

BH domains Bcl2 homology domains; there are four, BH1–4.

BH3-only proteins A group of pro-apoptotic proteins that have the BH3 domain but no other BH domains.

Caspases Cysteine proteases with aspartic acid specificity that are related to the *Caenorhabditis elegans* caspase CED-3 that is essential for programmed cell death in the worm.

ced genes Genes that implement programmed cell death in the worm *C. elegans*.

Apoptosis, the physiological cell death mechanism used by metazoans to remove unwanted cells, is controlled by a family of pro- and anti-apoptotic proteins that bear varying degrees of similarity to a protein called Bcl2. Some members of this family, such as Bcl2 itself, stop cells from dying, whereas other members of this family, such as Bax and Bak, are part of the mechanism that cells use to kill themselves.

Identification of Bcl2 as a Cell Death Inhibitor

A gene at the site of chromosomal translocations associated with the common lymphoid cancer, follicular lymphoma, was designated Bcl2 for B-cell leukemia/lymphoma gene number 2. Rather than promoting cell growth and proliferation like most cancer genes, Bcl2 does not stimulate cells to divide but prevents them from activating their endogenous apoptotic cell suicide mechanism. The association of activation of the apoptosis inhibitor Bcl2 with lymphoma was the first evidence that cell death is required to avoid the development of cancer.

Genetics of Cell Death in *Caenorhabditis elegans*

Although Bcl2 was the first component of the apoptosis mechanism to be recognized at the molecular level in any organism, genetic analysis of programmed cell death in the nematode *Caenorhabditis elegans* revealed that developmental cell death in worms is controlled and implemented by a specific genetic program. Programmed cell death in *C. elegans* fails to occur in *egl-1*, *ced-4*, and *ced-3* loss-of-function mutants, as well as in *ced-9* gain-of-function mutants, implying that *egl-1*, *ced-4*, and *ced-3* encode killer proteins, and that *ced-9* encodes a survival protein. The expression of human Bcl2 in the worm, and the cloning and sequencing of *ced-9*, showed that they are structurally and functionally homologous. In the worm, CED-9 prevents cell death by preventing the adaptor CED-4 from activating the protease CED-3, and in mammalian cells Bcl2 stops apoptosis by indirectly preventing activation of CED-3-like proteases, termed caspases.

Three Classes of Bcl2 Family Proteins

In vertebrates, apoptosis is regulated by three classes of Bcl2-like proteins that directly interact with each other. Members of this family all share regions of similarity termed Bcl2 homology (BH) domains. The three classes are (1) anti-apoptotic proteins such as Bcl2 itself, Bclx, and Mcl1; (2) pro-apoptotic proteins such as Bax and Bak; and (3) the pro-apoptotic BH3-only proteins, such as Puma, Noxa, Bad, Bim, and Bid, which only have a single BH domain.

The BH3-only proteins are the triggers of the death mechanism; Bcl2 and the anti-apoptotic proteins are like safety catches; and Bax and Bak can be thought of as the bullets.

When activated, Bax and Bak can form structures in the outer membrane of the mitochondria that allow cytochrome *c* to escape into the cytosol, where it binds to the CED-4 homolog Apaf-1, which, in turn, activates the protease caspase-9. Although Bax and Bak can activate spontaneously, this can be triggered by binding of BH3-only proteins, and is inhibited by binding of anti-apoptotic Bcl2 family proteins. Adding to the complexity of regulation of cell death, BH3-only proteins can also be bound by anti-apoptotic Bcl2 family members (Figure 1).

Interactions between Bcl2 family proteins determine whether and when a cell kills itself. For example, when the DNA in a cell is damaged, such as by ultraviolet (UV) light in sunshine, the cell detects the damage and increases levels of a protein called p53. In the nucleus, p53 turns on a number of genes, including the gene for the BH3-only protein Puma. Puma can cause activation of Bax and Bak by binding to them, as well as by binding to Bcl2, Bclx, and Mcl1, thereby preventing their inhibition of Bax and Bak. Either way, Bax and Bak activate and multimerize, to cause the outer mitochondrial membrane to become permeable, releasing cytochrome *c*, which activates Apaf-1 and caspases in the cytosol, culminating in cell death.

Therapeutic Implications

The initial cause of the malignancy follicular lymphoma is a chromosomal translocation that causes excess production of Bcl2 in a lymphocyte. Because of this, the cell and its progeny

Figure 1 Interactions between Bcl2 family members. (a) In healthy cells, BH3-only proteins such as Bim, Bad, Bid, Noxa, Puma (black), and Bax and Bak (white) are kept inactive by anti-apoptotic proteins such as Bcl2 (gray). When a cell receives a signal to die (b), levels of BH3-only proteins increase, and levels of anti-apoptotic proteins decrease. This frees Bax and Bak to spontaneously multimerize in the mitochondrial outer membrane (c), and multimerization is also facilitated by direct binding of BH3-only proteins. Multimerized Bax and Bak somehow allow cytochrome *c* to exit from the mitochondria to the cytosol, where it can bind to and activate Apaf-1 and caspases.

cannot kill themselves, and accumulate, eventually becoming malignant. The discovery that Bcl2 could be inhibited by BH3-only proteins prompted development of artificial BH3-only mimetic compounds that could be used to treat lymphoma. A compound called ABT-263 developed by Abbott is a Bcl2 antagonist that causes death of tumor cells by binding to Bcl2. It is currently in phase 2 clinical trials in humans.

Glossary

Bile acid Protonated bile salt.

Bile salt Organic anion with a steroid nucleus formed by enzymatic conversion of cholesterol (major human bile salts: cholate, chenodeoxycholate, deoxycholate, lithocholate, and ursodeoxycholate).

Bile salt transporters Membrane carrier proteins mediating the transport of bile salts across cell membranes. The Na⁺-taurocholate-cotransporting polypeptide (NTCP) at the basolateral hepatocyte membrane, the bile salt export pump (BSEP) at the apical hepatocyte membrane, and the apical sodium bile salt transporter (ASBT) at the apical membrane of ileocytes and cholangiocytes represent key carriers for the maintenance of an effective enterohepatic circulation of bile salts.

Cholestasis Impairment of bile formation and flow, caused by hepatocellular or cholangiocellular

secretory failure, intrahepatic or extrahepatic bile duct obstruction, or a combination of these factors, and leading to a retention of bile constituents in liver, serum, and other organs.

Enterohepatic circulation Effective recycling of bile salts from the intestine back to the liver, where bile salts can be resecreted into bile and intestine to fulfill their various functions as metabolic regulators and surfactants.

Nuclear hormone receptors Ligand-activated transcription factors regulating gene expression by interaction with specific DNA sequences. Bile salts have so far been identified to act as physiological ligands of the farnesoid X receptor (FXR), the pregnane X receptor (PXR), and the vitamin D receptor (VDR), thereby modulating their own metabolism and transport.

Introduction

Bile salts play a crucial role in hepatobiliary and intestinal homeostasis and digestion. The liver synthesizes primary bile salts from cholesterol. Secondary and tertiary bile salts with a similar molecular structure derive their individual properties from further chemical alterations by bacterial enzymes and the liver during their enterohepatic circulation.

Under physiological conditions, bile salts can solubilize lipophilic molecules in the intestine to enable their uptake from the lumen. Above a critical micellar concentration, molecular self-aggregation occurs, and micelles are formed. Internalization of hydrophobic molecules such as cholesterol, phospholipids, and monoglycerides into these mixed bile salt micelles promotes the absorption of dietary lipids and fat-soluble vitamins in the small intestine.

In addition to their function as a surfactant, bile salts are potent signaling molecules in the liver and intestine. In the small intestine, they play a key role in the defense against ascending microbes by farnesoid X-receptor (FXR)-dependent mechanisms and modulate hepatobiliary bile formation by FXR-controlled ileal release of the peptide hormone fibroblast growth factor 19 (FGF19). FGF19 regulates hepatocellular bile salt synthesis via its receptor, FGFR4, on hepatocyte membranes. Bile salts directly modulate their hepatocellular uptake, synthesis, and biliary secretion (and alternative basolateral release in cholestasis) at the transcriptional level via activation of nuclear receptors such as FXR and at the posttranscriptional level via modulation of cytosolic signaling cascades. This modulation

affects the synthesis and trafficking of bile salt transporters to their target membranes and thereby modifies hepatobiliary secretory capacity. Recent evidence indicates that bile salts also function as potent endocrine and paracrine messenger molecules within and outside the liver that affect a range of metabolic processes. These mechanisms are, in part, mediated via the bile salt membrane receptor, G-protein-coupled bile salt receptor, TGR5, which is expressed in various cell types except hepatocytes.

At high hepatocellular concentrations, hydrophobic bile salts may induce cholestasis, apoptosis, and necrosis. Bile salts with anticholestatic and antiapoptotic properties may be applied in clinical practice to modify the circulating bile salt pool in an effort to minimize bile toxicity while optimizing hepatobiliary function.

Biochemistry of Bile Salts

Bile salts consist of a steroid nucleus with its hydroxyl or other substituents and an aliphatic side chain of variable length. This steroid nucleus is similar to the core of steroid hormones and is an evolutionary strongly conserved structure.

In higher vertebrates and other modern animals, the majority of bile salts has a backbone of 24 carbon atoms. The bile salt pool of evolutionary predecessors is often dominated by molecules with 25–27 carbon atoms.

Protonation of bile salts changes them to their acid form. The salt form is more prevalent at a physiological pH (due to a pK_a of 4–5 for glycine-conjugated and unconjugated bile salts

Figure 1 Major bile salt biosynthetic pathways in the liver. The initial and rate-determining step of the classic (neutral) pathway is the conversion of cholesterol to 7 α -hydroxycholesterol by microsomal cholesterol 7 α -hydroxylase (CYP7A1) leading to formation of cholate and chenodeoxycholate. The initial step of the alternative (acidic) pathway is the conversion of cholesterol to 27-hydroxycholesterol by mitochondrial sterol 27-hydroxylase (CYP27A1) leading to formation mainly of chenodeoxycholate. These primary bile salts undergo further structural modifications by bacterial enzymes during enterohepatic cycling resulting in the formation of the secondary bile salts deoxycholate and lithocholate, and, by bacterial and hepatic enzymes, the tertiary bile salt ursodeoxycholate. Only major biosynthetic steps are shown. CYP7B1, oxysterol 7 α -hydroxylase; CYP8B1, sterol 12 α -hydroxylase; 7 α ,27-diOH-C, 7 α ,27-dihydroxycholesterol; 7 α ,12 α -diOH-C, 7 α ,12 α -dihydroxy-4-cholestene-3-one.

and a pK_a of about 1 for taurine-conjugated bile salts). Yet, the term 'bile acid' is often used in literature.

Synthesis of Bile Salts

Bile salts are mainly synthesized in the pericentral hepatocytes from cholesterol by different pathways, which involve up to 17 enzymes located in the endoplasmatic reticulum, mitochondria, cytosol, and peroxisomes (Figure 1).

The rate-limiting step of the classical bile salt biosynthetic pathway, also known as the neutral pathway, is 7 α -hydroxylation of cholesterol by a microsomal cytochrome P-450 monooxygenase (CYP7A1).

The alternative or acidic pathway is a second important route for bile salt synthesis, and is initiated by the mitochondrial enzyme sterol 27-hydroxylase (CYP27A1), which supports the conversion of cholesterol to both 27-hydroxycholesterol and 3 β -hydroxy-5-cholestenoic acid. CYP27A1 is present in some peripheral tissues, such as macrophages and vascular epithelium, and may thus add to the production of intermediate metabolites. For the final conversion to bile salts, they are transported to the liver where the full range of enzymes required for bile salt synthesis is present. Recently, functional bile salt formation was reported in the ovarian follicle, but the relevance of this finding remains to be explored.

The relative contribution of CYP7A1 and CYP27A1 to overall bile salt synthesis is unclear, but CYP7A1 has been estimated to account for 75% (mice) to 90–95% (human) of total bile salt synthesis under physiological conditions. Cholesterol 25-hydroxylase and cholesterol 24-hydroxylase may also initiate bile salt synthesis *in vitro*, but their contribution to total bile salt production may be limited.

Bile salt synthesis is highly regulated and subject to feedforward and feedback control whereby bile salts downregulate their own synthesis and oxysterols upregulate bile salt synthesis, mainly by regulating CYP7A1 gene transcription (Figure 2). Promoter analyses of the CYP7A1 gene have identified two highly conserved bile acid response elements and are binding sites for nuclear hormone receptors.

Nuclear hormone receptors are ligand-activated transcription factors with a strongly conserved DNA-binding domain (DBD) in the N-terminal region and a moderately conserved ligand-binding domain (LBD) in the C-terminal region. Upon ligand binding to the LBD, conformational changes in the nuclear receptors allow dissociation of corepressors and recruitment of coactivator proteins to activate the expression of target genes. The nuclear hormone receptor superfamily includes receptors for steroid and thyroid hormones, retinoids and vitamin A and D, as well as the bile-acid receptors FXR and pregnane X receptor (PXR).

Figure 2 Regulation of bile salt transport and metabolism by nuclear bile salt receptors in hepatocytes. The transport of bile salts is vectorial in the liver. Bile salts are taken up by the NTCP and OATP1B1/OATP1B3 in the sinusoidal membrane of hepatocytes and are excreted into bile mainly via BSEP in the canalicular membrane. Some bile salt metabolites are secreted into bile via the conjugate export pump (MRP2). FXR acts as a bile salt sensor and counteracts intracellular bile salt accumulation by inhibiting bile salt uptake and synthesis via upregulation of small heterodimer partner-1 (SHP-1) and transcriptional repression of CYP7A1 and NTCP genes. FXR also stimulates bile salt secretion by upregulating expression of apical BSEP and MRP2, and basolateral OST α/β . PXR represses bile salt synthesis by downregulation of transcription of CYP7A1 and stimulates bile salt detoxification by inducing expression of biotransformation phase 1 (e.g., CYP3A4) and phase 2 (e.g., SULT2A1) enzymes. PXR also stimulates the expression of the conjugate export pump, MRP2. 7 α -OH-C, 7 α -hydroxycholesterol ($\rightarrow$ activation; $\dashv$ repression).

Chenodeoxycholate (CDC) and cholate (C) are the endogenous ligands of FXR. In the liver, bile salt activation of FXR represses CYP7A1 transcription by an indirect mechanism involving nuclear receptors small heterodimer partner (SHP) and liver receptor homolog 1 (LRH1), or by a SHP-independent mechanism via FGF-19 and its receptor FGFR4. Activation of PXR, a promiscuous bile salt receptor, also results in repression of CYP7A1. The liver X receptor α (LXR α), abundantly expressed in the liver and activated by oxysterol ligands, has been shown to mediate the feedforward cholesterol catabolism to bile salts by upregulation of CYP7A1.

Bile salts can activate nuclear hormone receptor-independent pathways, such as protein kinase C (PKC) and mitogen-activated protein kinase (MAPK) signaling pathways. Activation of the G-protein-coupled bile salt receptor TGR5 induces an increase in intracellular cyclic adenosine monophosphate (cAMP), which may be an important mechanism in the regulation of energy homeostasis by bile salts and was shown to have an immunomodulatory effect on Kupffer cells.

Chemical Properties of Bile Salts

The end products of the complex biosynthetic steps from cholesterol to bile salts in humans are the two major primary bile salts, C (3 α ,7 α ,12 α -trihydroxy-5 β -cholanoate) and CDC (3 α ,7 α -dihydroxy-5 β -cholanoate). A final modification is the

conjugation of the terminal side-chain carboxylic acid with glycine or taurine by bile acid coenzyme A:amino acid N-acyltransferase (BAAT).

These (conjugated) primary bile salts undergo further modifications during enterohepatic cycling by bacterial enzymes in the distal intestine. Dehydroxylation at C-7 of C or CDC forms the secondary bile salts, deoxycholate (DC; 3 α ,12 α -dihydroxy-5 β -cholanoate) and lithocholate (LC; 3 α -hydroxy-5 β -cholanoate). Epimerization of the hydroxy group at the same C-7 position of CDC via the intermediate 7-ketolithocholate forms the tertiary bile salt ursodeoxycholate (UDC; 3 α ,7 β -dihydroxy-5 β -cholanoate).

The chemical properties of the different bile salts, such as their hydrophobicity, are determined by their molecular structure and conjugation. UDC is the most hydrophilic bile salt, followed by C, CDC, DC, and LC. Taurine-conjugated bile salts are more hydrophilic than glycine-conjugated ones, which are, in turn, more hydrophilic than free species.

The Bile Salt Pool

Bile is a mixture of 3–10 different species of bile salts, inorganic compounds such as ions and bicarbonate, and organic molecules such as bilirubin, phospholipids, cholesterol, adenosine nucleotides, albumin, and immunoglobulins.

Bile salts secreted into bile by hepatocytes originate from both their synthesis pathways as well as from their enterohepatic circulation. More than 95% of intestinal conjugated bile salts are actively reabsorbed, predominantly from the distal ileum by an apical sodium-dependent bile salt transporter (ASBT). After basolateral release into the mesenteric blood via the enterocyte organic solute transporter (OST), the OST α /OST β heterodimer, the bile salts, in part bound to albumin, reach the liver via the portal vein, to be reabsorbed and resecreted by the hepatocyte. The normal bile salt pool (about 3–4 g in humans) recirculates 5–10 times per day. As much as 5–10% of circulating bile salts are lost daily via the feces and are replaced by newly synthesized analogs.

Hepatic Transport of Bile Salts

The hepatocyte plays a key role in the vectorial transport of bile salts from the portal vein to the bile canaliculus, with distinct bile salt transport systems at its basolateral (sinusoidal) and apical (canalicular) plasma membranes (Figure 2). Functional impairment of bile salt transport at any level of the hepatocyte may be an important cause of cholestasis, a syndrome characterized by a reduction in bile flow and retention of biliary constituents in serum, liver, and other organs leading to biochemical, morphological, and clinical alterations.

Physiological Hepatocellular Bile Salt Transport

Bile salt uptake into the hepatocyte is predominantly mediated by the Na⁺-taurocholate-cotransporting polypeptide (NTCP), and, to a lesser extent, by the organic anion transporting protein (OATP) family. Transporters in the basolateral membrane, such as multidrug resistance-associated protein 4 (MRP4), can transfer conjugated bile salts back to the sinusoidal blood.

The exact nature of intrahepatocellular bile salt trafficking remains elusive. Bile salt-binding proteins are most likely involved in the rapid bile salt movement across the cell, and vesicular transport may also play a role.

Under physiological conditions, bile salt levels in the hepatocyte remain low. Efficient secretion of bile salts at the canalicular membrane is mainly achieved by the adenosine triphosphate (ATP)-dependent bile salt export pump (BSEP), which transports monovalent bile salts against a steep gradient (up to 1000-fold) across the apical membrane into the canaliculus. Mutations in this member of the ATP-binding cassette (ABC) transporter family may lead to progressive familial intrahepatic cholestasis type 2 (PFIC 2) in childhood, a severe disorder with markedly elevated serum bile salt levels and low content of bile salts in the bile. The conjugate export pump (MRP2) is another ABC transporter capable of transporting divalent sulfated and glucuronidated bile salts.

Active transport of bile salts across the canalicular membrane represents the rate-limiting step in the overall transport from blood to bile. It is under both short-term and long-term regulation by posttranscriptional and transcriptional mechanisms, respectively. On the transcriptional level, hepatic transporters have been shown to be regulated by nuclear receptors, such as FXR, which enhances BSEP expression in the

canalicular membrane of the hepatocyte. Bile salt-induced modulation of intracellular signaling cascades, including cytosolic free calcium [Ca²⁺]_i, isoforms of PKC and protein kinase A (PKA), mitogen-activated protein (MAP) kinase, and phosphatidylinositol 3-kinase (PI3K), contributes to bile salt-specific short-term regulation of bile secretion by the hepatocyte.

Cholestasis

In experimental models of cholestasis as well as in human cholestatic disorders, most of the hepatic uptake transporters are downregulated. Biliary secretion is further impaired by the retrieval of canalicular transporters from the plasma membrane and their storage in pericanalicular vesicles. Adaptive induction of basolateral bile salt exporter expression such as MRP3, MRP4, and OST α / β may protect the hepatocyte against rising intracellular concentrations of bile salts and other organic anions.

Bile Salts in Therapy

UDC is the major bile salt in black bear's bile, and has been used in Chinese traditional medicine in the form of dried black bear's bile for the treatment of icteric liver diseases for over 1000 years. UDC is normally present in human bile at a low concentration of 1–3% of total bile salts, but can comprise 40–50% of biliary bile salts in cholestatic patients treated with 13–15 mg per kg UDC per day. Its mechanisms of action are in part unraveled and include detoxification of bile, and stimulation of (impaired) hepatocellular and cholangiocellular secretion mainly by posttranscriptional mechanisms in hepatocytes and cholangiocytes, as well as antiapoptotic effects.

UDC is the established first-line treatment of primary biliary cirrhosis (PBC) and intrahepatic cholestasis of pregnancy (ICP). In PBC, UDC may normalize life expectancy in two-thirds of patients, may prolong transplant-free survival, delay histologic progression to fibrosis and cirrhosis, lower rates of complications of late-stage liver disease, and markedly improve serum liver tests. In ICP, UDC improves pruritus and serum liver tests in mothers and may prolong time to delivery and alleviate signs of fetal stress during pregnancy.

UDC is also widely used in other cholestatic disorders including primary sclerosing cholangitis (PSC), cystic fibrosis-associated liver disease (CFALD), or prolonged drug-induced cholestatic liver disorders due to its anticholestatic properties, although its long-term efficacy is not proven yet for these cholestatic conditions.

Cholate is effectively used for bile salt supplementation therapy in children with rare inborn errors of bile salt synthesis.

Increasing insight into the role of bile salts as important regulators of metabolic homeostasis, digestion, and intestinal defense has led to a steep increase in research efforts in the field of bile salt therapy. Several promising novel bile salt-derived compounds are at present under evaluation for therapeutic use in patients with cholestatic disorders, nonalcoholic fatty liver disease, as well as disorders of lipid metabolism.

Glossary

Nicotinoproteins NAD^+ - or NADP^+ -dependent oxidoreductases that bind the coenzymes tightly as prosthetic groups.

Oxidoreductase A coenzyme-dependent hydride transfer enzyme.

Pellagra Niacin-deficient nutritional condition.

Poly(ADPribose) polymerase NAD^+ -dependent enzyme that forms protein linked or unlinked chains of ADPribose.

Sirtuin NAD^+ -dependent protein lysine deacetylase related to yeast Sir2.

Nicotinamide Adenine Dinucleotide History and Structure

Nicotinamide adenine dinucleotide (NAD^+) was at the center of some of the greatest discoveries in the biological sciences in the early twentieth century. Originally termed cozymase or codehydrogenase I and later diphosphopyridine nucleotide (DPN), the activity was described in 1905 as a component of yeast extracts that accelerated cell-free alcoholic fermentation. Arthur Harden and William Young discovered that glycolysis proceeded slowly until a heat-stable and dialyzable cozymase fraction was added, which we now know contained NAD^+ , adenosine triphosphate (ATP), and Mg^{2+} . The NAD^+ component was later purified by Harden and Hans von Euler. In 1936, the structure of NAD^+ was determined independently by Otto Warburg and von Euler, and a role in oxidative metabolism was defined. Codehydrogenase II was found to be a triphosphopyridine dinucleotide, that is, nicotinamide adenine dinucleotide phosphate (NADP^+). Two salvageable precursors of NAD^+ , nicotinic acid (NA) and nicotinamide (Nam), were identified by Conrad Elvehjem in a search for non protein fractions from the liver that would reverse black spots on the tongues of dogs, an induced nutritional deficiency similar to pellagra, which was an epidemic in the American South in the early 1900s. Later, the basis for both *de novo* synthesis of NAD^+ from amino acids and salvage synthesis of NAD^+ was worked out. NA and Nam were collectively termed 'niacins'. The broad use of niacin supplementation has virtually eliminated pellagra.

NAD^+ is so termed because it consists of a Nam nucleotide, that is, nicotinamide riboside 5'-monophosphate, joined to the phosphate of an adenine nucleotide, that is., adenosine 5'-monophosphate. NADP^+ is formed when a phosphate group is added to the 2' position of adenosine (Figure 1). The glycosidic linkages between bases and ribosyl moieties are β in both nucleotides. The hydride-accepting moiety is the Nam base such that the plus signs on NAD^+ and NADP^+ refer to the oxidized, hydride-accepting forms. The overall charge of these molecules is negative because of the phosphates.

Salvage and De Novo Pathways

All dividing cells either form NAD^+ *de novo* from an amino acid and/or resynthesize NAD^+ from NA, Nam, and/or

nicotinamide riboside (NR). These water-soluble vitamins are NAD^+ breakdown products and metabolites that are transported systemically; these are available in the diet (Figure 2(a)).

NA is utilized by the Preiss-Handler pathway, which involves three enzymatic steps through nicotinic acid mononucleotide (NaMN) and nicotinic acid adenine dinucleotide (NaAD). In vertebrates, Nam is utilized in two enzymatic steps through nicotinamide mononucleotide (NMN). Since Nam can be converted into NA in many bacteria by a nicotinamidase not encoded in vertebrate genomes, Nam entry into the Preiss-Handler pathway in vertebrates is thought to depend on bacterial nicotinamidase in the gut. NR can be converted into two steps to NAD^+ through NMN, or can be converted into NAD^+ via splitting the nucleoside followed by Nam salvage. Specific transporters have been identified for the uptake of NA and NR, but not Nam or nicotinic acid riboside (NAR), an NAD^+ metabolite that can also be utilized by yeast at high doses.

Most organisms synthesize NAD^+ from either tryptophan or aspartic acid. *De novo* synthesis nearly always proceeds through quinolinic acid (QA) and NaMN, at which point NAD^+ is produced by the last two enzymes of the Preiss-Handler pathway (Figure 3).

The phosphorylated forms of NAD^+ are also generated by specific enzyme activities (Figure 2(b)). NADP^+ is generated from NAD^+ by NAD^+ kinase (NADK). In yeast, a mitochondrial NADH kinase generates NADPH from NADH. In addition, in bacteria and in animal mitochondria, the proton translocating, membrane-bound NADPH transhydrogenase interconverts NADPH and NAD^+ into NADP^+ and NADH. Thus, NADK activity is a gatekeeper of both phosphorylated forms of NAD^+ , and NADPH transhydrogenase allows a cell to maintain a redox balance in which NAD^+ levels exceed NADH levels, while NADPH levels exceed those of NADP^+ .

NAD^+ and NADP^+ in Redox Metabolism

Electron transfers that occur in oxidation-reduction (redox) reactions are essential to metabolism and life in all organisms. Redox reactions are catalyzed by a large family of enzymes called 'oxidoreductases'. The electron-donating species in a redox reaction is referred to as the reducing agent, or reductant, and the electron-accepting species is the oxidizing agent, or

Figure 1 NAD^+/NADH and $\text{NADP}^+/\text{NADPH}$ structure. NAD^+ is a dinucleotide consisting of a nicotinamide nucleotide, that is, nicotinamide riboside 5'-monophosphate (NMN) joined to the phosphate of an adenine nucleotide, that is, adenosine 5'-monophosphate (AMP). In NAD^+ , the X in the 2' position of the adenosine is an H, whereas in NADP^+ , a phosphate group is in the X position. The glycosidic linkages between bases and ribosyl moieties are β in both nucleotides. The Nam base is the hydride-accepting moiety, such that the plus signs on NAD^+ and NADP^+ refer to the oxidized, hydride-accepting forms.

oxidant. In biological redox reactions, the movement of electrons often occurs concomitant with the loss of hydrogen. This species is referred to as a hydride ion (:H^-).

In NAD^+ -dependent dehydrogenation reactions, NAD^+ and NADP^+ undergo reduction of the nicotinamide ring to form NADH and NADPH , respectively (Figure 1). In such reactions, a hydride ion is transferred to the carbon at the fourth position of the nicotinamide ring of NAD^+ (Figure 1). This transfer of hydride can happen in two ways. In A-type oxidoreductases, the hydrogen is transferred from above the plane of the nicotinamide ring to the front of the nicotinamide ring (A side), while B-type oxidoreductases transfer of the atom occurs from below to the backside of the nicotinamide ring (B side). This depends on how NAD^+ is oriented within the nucleotide-binding domain of the enzyme.

Oxidoreductases bind the NAD(P)^+ dinucleotide in a structural motif termed as a Rossmann fold (Figure 4(a)). The core Rossmann fold consists of one nucleotide-binding domain constructed from at least three β -strands flanked by two α -helices ($\beta\alpha\beta\alpha$), though some oxidoreductases have additional β -strands. There are four important motifs found within the Rossmann fold: a conserved positively charged residue (Arg or Lys) at the beginning of the first β -strand, a conserved negatively charged residue (Glu or Asp) at the end of the second β -strand, a phosphate-binding sequence –GXGXXG– and six conserved positions occupied by small hydrophobic amino acids.

Three of four conserved motifs within the Rossmann fold have well-defined nucleotide-binding, structural, or catalytic functions. The conserved positively charged residue (Arg or Lys) found at the beginning of the first β -strand is not well understood. It is thought to participate in stabilizing interactions with nearby β -strands, though these are not fully characterized. The conserved negatively charged residue at the carboxyl terminus of the second β -strand is used to bind the

2'-hydroxyl group of the adenine nucleotide. This site also helps to distinguish enzymes that bind NAD^+ from those that bind NADP^+ , as this residue is uncharged in enzymes that bind NADP^+ in order to accommodate the 2'-phosphate that takes the place of the hydroxyl. In NADP^+ -binding enzymes, the phosphate interacts with a nearby arginine residue instead. The phosphate-binding glycine-rich sequence (GXGXXG) resides in a loop between the first α -helix and β -strand. The first and second glycines are thought to allow important turns of the main chain in this loop. These turns promote an interaction between the main chain and the diphosphate bridge of NAD^+ to occur (Figure 4(b)). The third glycine promotes tight packing in the nucleotide-binding domain that prohibits NADP^+ from binding. NADP^+ -binding enzymes have a larger amino acid (alanine, serine, or proline) in the place of the glycine, which disrupts the close packing and allows NADP^+ to bind. Finally, the hydrophobic core, which contains six small hydrophobic amino acids, is necessary for maintaining the proper packing of the β -strands with respect to the α -helices. While these motifs form the proper tertiary structure and interactions to specify binding of NAD^+ versus NADP^+ , some enzymes, such as aldose reductase, glucose-6-phosphate dehydrogenase, and methylenetetrahydrofolate reductase, are exceptions to the rule, and bind both NAD^+ and NADP^+ .

For the majority of enzymes that do show a high level of specificity for either NAD^+ or NADP^+ , the preference often reflects the distinct metabolic role of the enzyme. NAD^+ is typically utilized in catabolic pathways in which energy is liberated from the oxidation of substrate molecules, whereas NADP^+ is most commonly utilized in anabolic reactions such as fatty acid synthesis and photosynthesis. The ratios of oxidized to reduced forms of NAD^+ and NADP^+ reflect these activities as well. In most tissues, in which it has been measured, the ratio of NAD^+ to NADH is high, providing ample NAD^+ to

Figure 2 NAD⁺ and NADP⁺ generation. (a) Cells have evolved pathways to salvage the pyridine ring of NAD⁺ from precursors NA, Nam, and NR, each of which is produced in the cell as metabolites and obtained in the diet as vitamins. Nicotinic acid (NA) is utilized by what is termed as the Preiss–Handler pathway, which involves three enzymatic steps. First, NA is converted into nicotinic acid mononucleotide (NaMN) by the nicotinic acid phosphoribosyltransferase enzyme (NAPRT). NaMN is subsequently converted into nicotinic acid adenine dinucleotide (NaAD), also called desamido NAD⁺, by nicotinamide mononucleotide adenyl transferase enzymes (NMNAT). Finally, NaAD is converted into NAD⁺ by the NAD⁺ synthetase enzyme (NADS). In mammals, salvaged Nam is utilized by a nicotinamide phosphoribosyltransferase enzyme (NamPRT). NamPRT catalyzes the addition of a phosphoribose moiety onto Nam forming nicotinamide mononucleotide (NMN). NMN is then converted into NAD⁺ by the NMNAT enzymes. Nam utilization differs among species. In some bacteria and fungi, Nam is converted into NA by a nicotinamidase enzyme (dotted line), after which it is utilized through the Preiss–Handler pathway to form NAD⁺. NR can be utilized through two distinct pathways. In an Nrk-dependent pathway, it is phosphorylated by nicotinamide riboside kinases (NRKs) to form NMN, which is converted into NAD⁺ by NMNAT enzymes. Alternatively, NR is utilized by purine nucleoside phosphorylase (PNP), which converts NR into Nam. Specific transporters have been identified that are responsible for the uptake of NA and NR. Another NAD⁺ precursor, that is not efficiently imported, but that can be produced intracellularly, is nicotinic acid riboside (NAR). NAR is phosphorylated by NRK to form NaMN, and is hydrolyzed to NA by PNP. Data in yeast *Saccharomyces cerevisiae* indicate that NR and NAR are generated by the activities of NMN/NaMN 5′-nucleotidases. (b) NADP⁺ and NADPH are generated from NAD⁺ and NADH by kinases (NADK and NADHK). NADPH transhydrogenase interconverts NADPH and NAD⁺ into NADP⁺ and NADH.

accept hydride ions from substrates, whereas the level of NADP⁺ is often significantly lower than NADPH promoting hydride transfer to substrate molecules from NADPH, as occurs in anabolic pathways. Likewise, the organelles in which these cofactors are primarily used are also distinct and reflective of their different activities. NAD⁺ is most often utilized in the mitochondria for oxidation of fuel molecules (pyruvate, fatty

acids, and α -keto acids), while NADPH serves as a reductant for fatty acid synthesis in the cytosol.

Hydride transfer from substrate to NAD⁺ has three prerequisites. First, the substrate must have high electron density on the carbon that donates the hydride. This is often ensured by interactions of the substrate with active site residues in redox enzymes. Similarly, the C4 carbon of the Nam ring of NAD⁺,

Figure 3 *De novo* biosynthetic pathways. (a) Present in most eukaryotic systems, the *de novo* pathway from tryptophan synthesizes quinolinic acid (QA) in five enzymatic steps. In the first step, tryptophan is converted into *N*-formyl-kynurenine by either indoleamine 2,3 deoxygenase (IDO) or tryptophan 2,3-dioxygenase (TDO). Formylkynurenine is subsequently converted into L-kynurenine by kynurenine formamidase (KFase). Kynurenine-3-hydrolase (K3H) produces 3-hydroxykynurenine from L-kynurenine, which is then a substrate of kynureninase (Kyase) to produce 3-hydroxyanthranilic acid. 3-Hydroxyanthranilate 3,4-dioxygenase (3HAO) then converts 3-hydroxyanthranilic acid into 2-amino-3-carboxy-muconate semialdehyde, which is converted into quinolinic acid by spontaneous cyclization. (b) Present in most prokaryotic systems, the *de novo* pathway from aspartic acid synthesizes QA in two enzymatic steps. Aspartate is converted into iminoaspartate by L-aspartate oxidase (AO), which is subsequently converted into QA by quinolinate synthase (QS).

which accepts the hydride ion, must have sufficiently low electron density to accept the hydride ion. Finally, the Nam moiety of NAD^+ must be positioned close enough to the hydride-donating species on the substrate to accept it. This is accomplished by the specific binding of NAD^+ in the Rossmann fold. For example, the active site of lactate dehydrogenase (LDH), an A-type oxidoreductase, utilizes an active site residue, histidine-195, as a general base. In catalysis, the histidine residue removes a proton from the hydroxyl group of the alcohol substrate promoting the hydride transfer from the hydroxyl group to the C4 position of the Nam moiety (Figure 5). Importantly, these mechanisms both avoid actual formation of the hydride ion, which is highly reactive, and cannot exist in water.

NAD^+ as a Prosthetic Group for Enzymes

In contrast to the reversible binding behavior of NAD^+ -coenzymes in redox reactions, these cofactors can also function as tightly bound prosthetic groups. In such enzymes, NAD^+ and NADP^+ do not dissociate with the release of the product,

but stay tightly bound. Enzymes that catalyze reactions using a prosthetic group often have higher turnover rates than enzymes that allow the coenzyme to dissociate by virtue of eliminating slow association and dissociation steps. In addition, enzymes that bind and sequester a cofactor in the active redox state are rendered insensitive to regulation due to the redox state of the cell. This is due to the enzyme's ability to return the bound coenzyme to its original active redox state after catalysis so that it can perform subsequent reactions. Enzymes accomplish this in several ways. First, the enzyme can participate in alternating oxidation and reduction reactions with different substrates. Alternatively, the bound coenzyme can be reoxidized or reduced by a nonsubstrate molecule, such as ferredoxin. In other reactions, the coenzyme can transiently oxidize or reduce a substrate, but return to the original redox state prior to product release. Finally, in some reactions, the coenzyme can accept only a pair of electrons and not the entire hydride ion. In this way, the bound coenzyme can promote catalysis without full oxidation or reduction occurring, eliminating the regeneration requirement. Enzymes that bind NAD^+ and NADP^+ as prosthetic groups are termed

'nicotinoproteins', which belong to a superfamily of metallo alcohol dehydrogenases.

Nonredox Roles

In addition to its coenzymatic functions, NAD^+ is a consumed substrate of multiple families of enzymes (Figure 6). Generally termed as glycohydrolases, these enzymes cleave the glycosidic bond between the nicotinamide and adenosine diphosphate (ADP)ribose moieties of NAD^+ .

One class of NAD^+ -consuming enzymes possesses ADP-ribose transferase (ART) and poly(ADP-ribose) polymerase (PARP)

activities, which transfer and/or polymerize NAD^+ -derived ADP-ribose to target molecules. PARP activity, which is considered one of the major NAD^+ -consuming activities within the cell, is upregulated in response to genome damage. Individual members of the PARP family have been shown to mediate diverse cellular responses including inflammation, intracellular trafficking, and cell death.

A second class of NAD^+ -consuming enzymes consists of cyclic (ADP-ribosyl) synthases, which are largely extracellular enzymes that consume NAD^+ to produce and hydrolyze cyclic-ADP-ribose. These activities are particularly important for calcium (Ca^{2+}) regulation within the cell, as cyclic-ADP-ribose is a potent Ca^{2+} -mobilizing second messenger.

Figure 6 Nonredox roles of NAD^+ . Enzymes that cleave the glycosidic bond between the nicotinamide and ADP-ribose moieties of NAD^+ are termed glycohydrolases. These include ADP-ribose transferase (ART) and poly(ADP-ribose) polymerase (PARP) activities, which attach NAD^+ -derived ADP-ribose to target molecules, and cyclic ADP-ribose synthases, which consume NAD^+ to produce and hydrolyze cyclic-ADP-ribose. In addition, sirtuins catalyze NAD^+ -dependent protein lysine deacetylation by conversion of a lysine-acetylated peptide to a deacetylated peptide with production of 2'-O-acetyl-ADP-ribose and Nam as products.

A third class of NAD^+ -consuming enzymes is sirtuins, the NAD^+ -dependent protein lysine deacetylases related to yeast Sir2. These enzymes convert a lysine-acetylated peptide into a deacetylated peptide with the production of 2'-O-acetyl-ADP-ribose and Nam as products. This process has been implicated in gene regulation, enzyme activity, and longevity.

NAD^+ Alterations in Aging

Calorie restriction (CR) is a powerful means to extend life span in model organisms. In yeast, Sir2 plays a role in mediating the effect of CR on extension of life span. Since NAD^+ is involved in glucose utilization and is an essential Sir2 substrate, its metabolism is one potential subsystem that may be altered by CR. Among the proposed mechanisms, it is conceivable that the NAD^+/NADH ratio, the NAD^+/Nam ratio, altered flux, and/or increased net synthesis may regulate sirtuin activities.

PARP activities may also influence the aging process in an NAD^+ -dependent manner. In particular, the DNA-damage surveillance activity of PARP has been proposed as a critical factor to reduce genotoxic stress, maintain genomic stability, and promote cellular survival. PARP family enzymes, tankyrase-1 and tankyrase-2, are also involved in the maintenance of telomere length, which has been implicated in the regulation of aging. Roles in aging and telomere maintenance are underscored by the observation that PARP-1, tankyrase-1, and tankyrase-2 interact with the Werner syndrome protein, which is altered in progeric humans.

Human Health and Disease

Widespread use of niacins has largely eliminated pellagra, whereas high-dose NA is widely used for dyslipidemia and high-dose Nam has been tested for efficacy in stroke and other conditions. Since high-dose NA causes a flushing response and high-dose Nam may inhibit sirtuins and other NAD^+ -consuming enzymes, NR is being tested for effectiveness in the

therapy of neurodegenerative diseases, such as Alzheimer's and Parkinson's disease.

Many of the enzymes that use NAD^+ either as a co-enzyme or as a substrate are considered as potential targets for drug design. Although redox enzymes bind NAD^+ in a conserved binding pocket, enzyme-specific inhibitors based on the structure of NAD^+ have been developed. For example, the nucleoside analog tiazofurin, which is converted in the cell into a toxic analog of NAD^+ , tiazofurin adenine dinucleotide, is a potent prodrug inhibitor of IMP dehydrogenase (IMPDH), an enzyme important in *de novo* purine synthesis that might be targeted in malignancies, viral infection, and/or for the purposes of immunosuppression.

NAD^+ biosynthetic pathways have also been targeted, especially for antibiotic development. The differences in NAD^+ biosynthetic pathways and enzymes between humans and lower organisms make the development of specific inhibitors to block NAD^+ synthesis in infectious organisms a plausible path to antibiotics. So far, drugs of this nature have been used to target *Mycobacterium tuberculosis*, the tuberculosis-causing bacterium. Isonicotinylhydrazine is a Nam-related anti-tuberculosis agent that is metabolized to form inhibitors of redox enzymes. It is anticipated that additional agents will be developed against genetically validated enzymes, potentially using structure-based drug design and/or high-throughput screening.

Glossary

Cardiogenesis Development of the heart during embryonic development.

MicroRNA (miRNA) Single-stranded RNA molecules about 21–23 nucleotides in length that act as negative regulators of gene expression by interacting with specific mRNA targets and inhibiting translation or promoting mRNA degradation.

Myogenesis The formation of muscle fibers and skeletal muscle during embryonic development.

Sarcomere The basic contractile unit of the muscle cell that is arranged in distinct bands to give muscle its striated appearance.

Satellite cells A resident skeletal muscle stem cell population located in a quiescent state under the basal lamina of skeletal muscle fibers that upon muscle injury are activated to proliferate, differentiate, and repair damaged muscle.

Somites Spherical masses of primordial muscle tissue that occur at regular intervals along the length of the embryo that form skeletal muscle in the vertebrate limb and trunk.

Transcription factor A protein that binds to specific DNA sequences and activates or represses gene expression.

Introduction

Cardiac and skeletal muscles are defined as striated muscles because under the microscope they appear striped or striated in appearance due to the arrangements of the sarcomeres in distinct bands (Figure 1). The sarcomere is the basic contractile unit of the muscle cell and is comprised of bands termed A, M, I, and Z lines. The A band comprises the thick filaments of myosin and proteins that bind myosin. The M line is the middle part of the A band and the I band is composed of thin actin filaments and proteins that bind actin. The Z line, situated in the middle of the I band, contains the greatest number of sarcomeric proteins and functions as a scaffold that links the sarcomeric contractile units in series. It is the Z line that defines the lateral boundaries of the sarcomere. Although the sarcomere appears to be in an organized static state, it is well recognized that sarcomeric proteins have a dynamic distribution within the cell and can communicate signals between the sarcomere and the nucleus to participate in the response of the muscle cell to changes in the structure or function of the contractile machinery. Indeed, the importance of the cytoarchitecture of the sarcomere is underscored by the observation that mutations of sarcomeric proteins are associated with a large percentage of cardiac and skeletal muscle myopathies in humans.

This article provides an overview of the biochemistry of striated muscle development, highlighting the differences between cardiac and skeletal muscles. Emphasis is given to embryonic cells adopting specific cell fates and how these cells then differentiate to become cardiac or skeletal muscle. In particular, many of the transcription factors and microRNAs (miRNAs) that regulate the programs controlling cell differentiation and morphogenesis during development are described. Of note, the processes involved in muscle development are evolutionarily conserved across diverse organisms. This enabled many of the myogenic regulatory processes to be identified in fruit flies, zebrafish, chick, mouse, and humans, and validated by performing gain- and loss-of-function experiments

in vivo and *in vitro*. It is the integration and collaboration of developmental biology and molecular biology research studies that have systematically defined the factors involved in determining the regulatory processes necessary for striated muscle development.

Development of Skeletal Muscle

Myogenesis

Although both cardiac and skeletal muscles are striated muscles, they originate and develop from distinct cell populations. Skeletal muscle is derived from somites of the embryo, which are the spherical masses of primordial muscle tissue that occur at regular intervals along the length of the embryo (Figure 2). At the onset of myogenesis in the somite, progenitor cells delaminate from the dermomyotome to locate to the underlying myotome. The dermomyotome gives rise to all skeletal muscle of the trunk and limbs. As myogenesis proceeds, primitive cells become myoblasts, which are cells committed to become skeletal muscle. Myoblasts proliferate, migrate, and aggregate into clusters, and fuse to become multi-nucleated myotubes. Further lengthening occurs by fusion of more myoblasts with the ends of the myotubes. Primary myotubes, the first formed myotubes, separate into clusters and are surrounded by the basal lamina. More myoblasts aggregate beneath the basal lamina and fuse to form secondary myotubes. With further development, the primary myotube begins to look like mature skeletal muscle with the nuclei being forced from the center to the periphery as the myofiber is filled with contractile proteins. Secondary myotubes also begin to mature into fibers so that the primary and secondary myotubes are contained within a single basement membrane. As myogenesis proceeds, skeletal muscle fibers develop into slow twitch or fast twitch, based on the type of nerve innervation and spatiotemporal expression of regulatory factors. It is the heterogeneity of muscle fibers within the muscle bed that provides the differences in the physiological and metabolic parameters of the muscles, enabling different muscle groups to

provide a variety of functional properties in response to environmental demands.

Skeletal muscle throughout the body is not derived from the same cell population. The trunk and limb muscles are derived from the somite but the head and neck muscles (termed the branchiomeric muscles) are derived from the mesodermal core of the branchial arches and from the prechordial mesoderm. Of interest, recent studies using molecular biology tools have shown a close relationship between the origin of head skeletal muscle and heart muscle. The term ‘cardio-craniofacial

morphogenetic field’ reflects the intimate developmental relationship between the head, face, and heart.

The Role of Transcription Factors in Skeletal Muscle Development

Skeletal muscle development is controlled by a network of evolutionarily conserved regulatory factors that specify myogenic progenitor cells and direct them to muscle differentiation. Some of the regulatory factors that are critical for the

determination and terminal differentiation are restricted to skeletal muscle, such as the four myogenic regulatory factors (MRFs): MyoD, Myf5, myogenin, and MRF4 (Figure 3). Other skeletal muscle regulatory factors, such as myocyte enhancer factor 2 (MEF2), are more broadly expressed in a variety of tissues, such as cardiac and smooth muscle, T cells, and brain. It is the cooperative interactions of the MRFs with MEF2 proteins in the context of various signaling pathways that regulate myogenesis of skeletal muscle.

MRFs were discovered over two decades ago and have the unique distinction of converting a variety of cell types to myoblasts. MRFs are DNA-binding proteins that contain a basic helix–loop–helix (bHLH) domain and bind to an E-box consensus sequence (CANNTG) which is present in the promoters and enhancers of many muscle-specific genes. *In vitro*, the MRFs appear indistinguishable; however, *in vivo*, primarily due to different spatiotemporal expression patterns, they have distinct roles. During embryogenesis Myf5 is expressed in the dorsal–medial somites, which give rise to the trunk and intercostal muscles, followed by MyoD expression in the dorsal–lateral somites, which give rise to the body wall and limb muscles. Myogenin plays a critical role in terminal differentiation of myoblasts and MRF4 has a complex temporal expression pattern during embryogenesis, suggesting roles in both muscle determination and terminal differentiation. It is of interest that although *in vitro* MRFs can substitute for one another, *in vivo*, genetic engineering studies showed that *myogenin* inserted into the *myf5* locus was not able to completely

replace the function of Myf5 in muscle development, suggesting that each gene has a unique function *in vivo*.

MEF2 factors alone do not possess myogenic activity but, in combination with the MRF transcription factors, drive and amplify the myogenic differentiation program. There are four MEF2 genes (*Mef2a*, *b*, *c*, and *d*) in vertebrates and they bind to the consensus DNA sequence YTA(A/T)₄TAR which is present in many muscle-specific gene promoter and enhancer regions. In addition to regulating numerous muscle structural genes, MEF2 proteins regulate the expression of the MRF genes, such as myogenin, thereby providing a positive feed-forward loop that perpetuates and amplifies the decision to differentiate. Further, MEF2 interacts with additional transcription factors that are required for proper muscle development. Similar to MRFs, MEF2 is expressed in the somites. However, unlike the restrictive expression pattern of the MRF proteins in skeletal muscle, MEF2 proteins are expressed in many cell types, including neurons, chondrocytes, and cardiac, skeletal, and smooth muscles. Of interest, the expression of MEF2 in all these various cell types occurs concomitantly with the activation of the differentiation programs in different cell types. The activity of MEF2 is tightly governed by class IIa histone deacetylases (HDACs), which directly bind and promote the formation of multiprotein repressive complexes on MEF2-dependent genes. It is the balance between the transcription-activating functions of MEF2 and the repressive functions of class IIa HDACs that dictates tissue development.

Figure 3 Pathways during skeletal muscle development. (a) Stages of myogenesis. (b) Regulatory pathways during myogenesis. Image by José Cabrera.

Pax3 and Pax7 are transcription factors that belong to the conserved Pax gene family and consist of a paired domain that confers sequence-specific binding to DNA, an octapeptide and a homeodomain. Pax3 and Pax7 are expressed in distinct areas of the somite and play a key role during myogenesis in regulating myogenic cell fate. Pax3 is transcribed throughout the somite before becoming restricted to the dermomyotome and Pax7 is expressed in the central domain of the dermomyotome. During myogenesis, Pax3 regulates the MRFs by directly activating the *Myf5* gene, and eventually forming the trunk and limb skeletal muscles. Pax3 and Pax7 not only regulate the entry of progenitor cells into the myogenic program but also control critical aspects of cell survival, proliferation, and migration. In addition, Pax3 and Pax7 also mark a reserve population of myogenic progenitor cells, called satellite cells (see below for more information), which are involved in regeneration.

In humans, translocation of the PAX3 and PAX7 gene to the *FKHR* locus on chromosome 13 produces a skeletal muscle tumor, called alveolar rhabdomyosarcoma. The gene fusions give rise to an in-frame PAX-FKHR chimeric transcription factor, in which the PAX DNA-binding domains are fused to the transcriptional activation domain of FKHR. PAX-FKHR has been shown to drive the generation of discrete nucleated cells from differentiated myofibers and thereby cause neoplastic transformation of skeletal muscle.

Although the branchiomic muscles of the head, like the skeletal muscles of the rest of the body, require MRFs for differentiation, many of the transcription factors involved in specifying myogenic progenitors in the head are just beginning to be discovered and appear to be distinct from those in the trunk. Myogenesis in the head does not depend on Pax3 and Pax7 in the same way as the trunk and limb muscles. Pax3 is not expressed in head muscles, and Pax7, although present in the myogenic cells of the branchial arches that give rise to facial muscles, is expressed after *Myf5* and *MyoD*. Other transcription factors, *Pitx2*, the T-box gene *Tbx1*, and the bHLH genes *capsulin/Pod-1/epicardin/Tcf21* and *MyoR/musculin* encode transcription factors that play roles in specifying progenitor cells that will give rise to branchiomic muscles of the head. *Pitx2* is expressed well before the onset of myogenic progression in the first branchial arch mesodermal core and is essential for the formation of first branchial arch-derived muscle groups. *Pitx2* contributes to the network that specifies pre-myogenic progenitors for extraocular and mastication muscles. *MyoR/musculin* and *capsulin/Pod-1/epicardin*, are transcription factors expressed in specific facial muscle precursors. *MyoR* and *capsulin* are transiently expressed in migratory paraxial mesodermal cells in the branchial arches that appear to represent precursors of the muscles of mastication.

Myostatin, a TGF- β family member, is a secreted protein that acts as a negative regulator of skeletal muscle mass. During embryogenesis, myostatin is expressed by cells in the myotome and in developing skeletal muscle and acts to regulate the final number of muscle fibers that are formed. Myostatin signaling acts on embryonic muscle progenitor cells (*Pax7⁺/Myf5⁺*) that have entered the muscle masses to limit their proliferation by activating p21 and *MyoD* expression. Myostatin affects the balance between proliferation and differentiation of embryonic muscle progenitors by enhancing

their terminal differentiation. Of note, a toddler born with a genetic mutation in the *myostatin* allele developed bulging arm and leg muscles twice the size of other kids his age. This shows that a genetic mutation in myostatin, a negative regulator of skeletal muscle mass, causes a human to naturally build muscle.

The Role of miRNAs in Skeletal Muscle Development

Recent evidence supports a role for miRNAs as integral components of the regulatory circuitry for muscle development. miRNAs are small RNAs that are transcribed as larger transcripts (pri-miRNAs) that are processed by Droscha into stem-loop precursors (pre-miRNAs). The pre-miRNAs are transported from the nucleus to the cytoplasm and subsequently cleaved by Dicer to yield a 20–22-nucleotide mature miRNA. miRNAs act as negative regulators of gene expression by interacting with the 3'-untranslated regions (UTRs) of specific mRNA targets and inhibiting translation or promoting mRNA degradation. The primary determinant of binding specificity to complementary target mRNAs is determined by Watson-Crick base pairing of nucleotides 2–8 at the 5'-end of the miRNA, referred to as the 'seed sequence'. However, nucleotides outside of this region also influence mRNA repression, as does the secondary structure of the surrounding regions of the mRNA 3'-UTR sequence, the number and spacing of target sites, and the location of the miRNA target site relative to the open reading frame. While some miRNAs may exert their effects through pronounced repression of a relatively small number of mRNA targets, more commonly, miRNAs regulate dozens or hundreds of targets by relatively subtle changes in expression. Computational-experimental analyses suggest that approximately 30% of human mRNAs are miRNA targets. It is most likely the summation of the changes in multiple mRNAs that causes the phenotypic effects of miRNAs.

The skeletal muscle miRNAs, miR-1, miR-133, and miR-206, regulate skeletal myoblast proliferation and differentiation. miR-1 and miR-133, both expressed in striated muscle, are generated from a common bicistronic transcript. It is believed that the miR-1/133 locus was evolutionarily duplicated twice to generate the miR-1-2/133a-1 locus, also expressed in striated muscle and the miR-206/133b locus, which is only expressed in skeletal muscle.

The importance of miRNA processing for muscle development and function was demonstrated when skeletal muscle-specific deletion of the Dicer allele resulted in perinatal lethality due to skeletal muscle hypoplasia. As myogenesis progresses from the myoblast stage to the myotube stage, the level of the muscle-specific miR-133 increases and miR-133 represses expression of serum response factor (SRF), a positive regulator of miR-1/133 expression and repressor of myoblast proliferation, thereby establishing negative feedback loops within muscle cell lineages. MEF2 establishes an additional level of myogenic regulation by regulating the expression of miR-1 and miR-133. miR-1 represses expression of HDAC4, a repressor of MEF2 activity, thereby establishing a negative feedback loop to modulate miR-1 and miR-133 expression and promoting myoblast differentiation. Thus, miR-1 upregulation during differentiation is a mechanism to reduce HDAC4 expression and to potentiate MEF2 pro-myogenic activity. miR-206, generated

from a bicistronic transcript that also encodes miR-133b, is exclusively expressed in skeletal muscle. miR-206 is expressed during myogenesis and is involved in the formation of differentiated skeletal muscle cells.

Of interest, a genome scan done on Texel sheep, renowned for their exceptional meatiness, showed a mutation in the myostatin gene that created an illegitimate miRNA target site. The spontaneous mutation of a G-to-A in the 3'-UTR creates a target site for miR-1 and miR-206 resulting in translational inhibition of the *myostatin* gene and dramatic muscularity in the Texel strain of sheep. This enhancement in muscle mass mimics the phenotype seen in mice and humans with mutations in the *myostatin* gene.

Development of Cardiac Muscle

Cardiogenesis

Heart development begins when mesodermal progenitor cells within a bilaterally symmetrical region of the embryo, known as the cardiac crescent or primary heart field, adopt a cardiac fate in response to inductive cues from surrounding tissues. Soon thereafter, these cells converge along the midline of the embryo to form a linear heart tube. Generation of the mature multi-chambered heart from the linear heart tube involves a complex series of events that include rightward looping and diversification of cardiac cell types, balloon-like growth and septation to form the cardiac chambers, and connection to the inflow and outflow tract vasculature (Figure 4).

In the developing heart, there are two heart fields, termed the primary and the secondary heart fields. This designation is based on both the timing of entry of the precursor cells into the heart and the timing of differentiation. The primary heart field, which generates the linear heart tube, serves as the source of precursors of the left ventricle and atrial chambers. The secondary heart field, a population of cardiac precursor cells, is derived from a region of the splanchnic mesoderm, medial to and distinct from the primary heart field that makes up the cardiac crescent. Cells from the secondary heart field are added to the anterior region of the heart tube at the onset of looping and give rise to the outflow tract and right ventricle. Cells from the secondary heart field, in addition to giving rise to the heart, also contribute to the branchiomeric muscles of the head that

are involved in operating the jaw, facial expression, feeding, and breathing.

The outermost surface of the heart is covered by the epicardium. The epicardium develops as a monolayered, squamous epithelial sheet. During the process of cardiac looping, cells of the epithelial proepicardium migrate anteriorly from the proepicardial organ at the posterior end of the heart to cover the surface of the myocardium to form the epicardium, which persists through development and adulthood. It was initially thought that the epicardium was a mere protection to the heart; however, recent new findings have shown that the epicardial cells are important as the origin of part of the coronary system and cardiac interstitial/fibrous cells. A subpopulation of cells from the epicardium undergoes an epithelial-mesenchymal transformation, infiltrating the heart and giving rise to smooth muscle, vascular endothelium, and cardiac fibroblasts of the coronary vasculature. In addition to serving as a source of progenitor cells and signals that are critical for normal heart development, recent studies revealed an unexpected role for the epicardium in myocardial repair following injury.

The Role of Transcription Factors in Cardiac Muscle Development

In contrast to skeletal muscle in which any member of the MRF family can convert a variety of cell types to skeletal muscle myoblasts, there is no single transcription factor that can transform cells to cardiac cells *in vitro*. However, over the decades, studies of heart development have revealed an evolutionarily conserved gene regulatory network consisting of functional interconnections between myogenic transcription factors, their downstream target genes, and upstream signaling pathways that direct cardiac cell fate, myocyte differentiation, and cardiac morphogenesis. In fact, the fruit fly (*Drosophila melanogaster*) has provided a powerful model for delineating the foundation of the cardiac regulatory network. The *Nkx2.5* gene encoding a transcription factor considered to be a cardiac specifier was initially discovered in the fruit fly, in which it was found to be required for a heart development and called *tinman*.

In vertebrate embryos, cardiac precursor cells are specified by signals from adjacent noncardiogenic tissues. Signals from

Figure 4 Illustration of the stages of cardiogenesis. Image by Ryan Carre.

the transforming growth factor (TGF)- β superfamily (bone morphogenetic protein (BMP)2/4, TGF- β s, and activin) and the fibroblast growth factor (FGF) family (especially FGF2, 4, 8) are secreted from surrounding tissues to promote the specification of myocardial fate and induce cardiogenesis. In addition, there is evidence that noncanonical Wnt and Sonic hedgehog (Shh) signaling facilitate myocardial induction.

The cardiac progenitors of the primary heart field express both BMP2/4 and Nkx2.5. Nkx2.5, the first cardiac marker gene to be expressed, occupies the center of the transcriptional circuitry, which confers commitment and determination of the heart field precursor cells to a myocardial fate. Nkx2.5 is involved in activation of other transcription factors such as SRF, GATA4/6, Mef2c, Tbx5, and Hand1/2, which impact the transcription of genes involved in the myocardial contractile apparatus and sarcomeric proteins (Figure 5).

The activity of SRF, a transcription factor that binds DNA at a CArG box, is controlled to a large extent by its interaction with tissue-specific regulatory cofactors. There are a large number of SRF cofactors, including GATA4 and Nkx2.5, which form complexes with each other and with SRF. Myocardin, expressed concomitantly with Nkx2.5, is a potent activator of SRF. Remarkably, mis-expression of myocardin can activate cardiac genes even in spinal cord neurons and can convert fibroblasts into smooth muscle cells. Thus, under certain conditions, myocardin acts as a master regulator of cardiovascular cell fates.

The GATA family of zinc-finger-containing genes has been shown to be involved in the progression of differentiation of the mesodermal progenitor cells to a cardiac fate. In the heart, GATA4 is expressed in cardiomyocytes and their mesodermal precursors, as well as in the endocardium and the epicardium. GATA4 binds to and regulates expression of a number of myocardium-expressed genes. GATA factors have been shown to be involved in the migration of the cardiac progenitor cells to form the heart tube and in controlling cell survival in cardiomyocytes. In humans, haploinsufficiency of GATA4 can result in cardiac septal defects.

MEF is expressed in cardiac cells and regulates other transcription factors necessary for heart formation. MEF2 autoregulates its expression and activates a myriad of cardiac-specific genes. MEF2 also controls the timing and magnitude of muscle

gene expression *in vivo* by recruiting HDACs, which act as transcriptional repressors. The interaction of HDACs with MEF2 is a key determinant of heart size from embryonic life to adulthood; mutations in these genes leads to a spectrum of cardiac defects that include ventricular hypoplasia, ventricular-septal defects, and cardiac sudden death.

Members of the T-box transcription factor family are characterized by the presence of a highly conserved 180-amino acid, sequence-specific, DNA-binding domain termed the T-box. T-box proteins function as transcriptional activators or repressors depending on the cell context and have been shown to be crucial to heart development. At least seven members of the T-box gene family are expressed in the embryonic heart in humans and vertebrate models, namely Tbx1-5, Tbx18, and Tbx20, and these genes show overlapping expression patterns in the first and second heart precursor lineages, the myocardium, the endocardium and valves, the conduction system, and the epicardium. Of interest, several human congenital anomaly syndromes have been linked to T-box gene haploinsufficiency.

An important insight into the genetic circuitry of ventricular development was provided by the discovery of two chamber-restricted bHLH transcription factors, Hand1 (also known as eHand/Thing-1/Hxt) and Hand2 (also known as dHand/Hed), which are expressed in the left and right ventricular chambers, respectively. Hand1 expression demarcates the primary heart field, which gives rise to the left ventricle. Hand2 is expressed throughout the linear heart tube before becoming restricted predominantly to the right ventricular chamber. Mice lacking Hand2 fail to form a right ventricle and mice lacking both Hand1 and Hand2 form neither ventricle. These mutant mice were the first to demonstrate that a single gene mutation could result in the ablation of an entire segment of the heart. Clinicians have long known that congenital heart defects in humans typically affect specific structures of the heart, such as the right or left ventricles, leaving the rest of the heart intact. The lack of ventricles in HDAC1/2 mutant mice supports the notion that the heart is assembled in a modular fashion in which each compartment is governed by unique genetic programs. In humans, mutations in the *HAND* genes are associated with hypoplasia of the heart, the most severe form of congenital heart disease.

Figure 5 Regulatory pathways during cardiogenesis. Modified from Muñoz-Chápuli R and Pérez-Pomares JM (2010) Cardiogenesis: An embryological perspective. *Journal of Cardiovascular Translational Research* 3: 37–48, with permission from Springer.

Another family of bHLH transcription factors with important functions in cardiovascular development is the hairy-related transcription factor (Hrt) family, also known as Hey, Hesr, CHF, and Herp factors. During embryogenesis, Hrt genes show highly specific expression patterns that demarcate regions of the developing heart, vasculature, pharyngeal arches, and somites. Hrt proteins function as transcriptional repressors downstream of Notch signaling, which regulates binary cell fate decisions during development. Upon activation by ligands, such as Delta and Jagged on the surfaces of adjacent cells, the intracellular domain of the Notch receptor is cleaved and translocated to the nucleus where it cooperates with CSL/RBP-Jk to stimulate transcription of Hrt genes. Hrt expression then fulfills a negative feedback loop to modulate further Notch signaling, thereby resulting in a transient or periodic signal. In addition to binding to an E-box DNA sequence motif, Hrt proteins interact with GATA factors and repress GATA-dependent transcription and cardiomyocyte hypertrophy.

MyoR and capsulin are related bHLH proteins that are co-expressed in branchiomic muscles and the primary heart field. Both genes also show unique expression domains in trunk skeletal muscle precursors and in derivatives of the lateral and intermediate mesoderm. Capsulin also marks the proepicardial organ and developing epicardium and, after birth, is expressed in a population of cells associated with the coronary vasculature. MyoR and capsulin mutant mice have revealed these genes to play redundant roles in specification of branchiomic muscles and show MyoR and capsulin as unique transcriptional regulators for the development of specific head muscles.

The secondary heart field builds the right ventricle and the outflow tract including its myocardial, smooth muscle, and endothelial investments, as well as parts of the atria. Islet1 (Isl1), a LIM-homeobox transcription factor is expressed in the secondary heart field and has been defined as a marker for a cardiac progenitor cell lineage that is capable of differentiating into all three major cell types of the heart: cardiomyocytes, smooth muscle, and endothelial cell lineages. More importantly, isolated progenitor cells expressing Isl1 are capable of self-renewal and expansion before differentiation into the three major cell types in the heart. These Isl1-positive cells serve as a cardiac stem cell population and offer novel opportunities for human regenerative cardiovascular medicine.

Most recently, it was reported that a combination of three developmental transcription factors, Gata4, Mef2c, and Tbx5, rapidly and efficiently reprograms dermal fibroblasts into differentiated cardiomyocyte-like cells. Although no single master regulator has been identified to direct cardiac reprogramming, this report shows that functional cardiomyocytes can be directly reprogrammed from differentiated somatic cells by defined factors. This discovery provides new prospects for an easy, accessible source of cardiomyocytes for regenerative approaches to combat heart disease.

The Role of miRNAs in Cardiac Muscle Development

Similar to skeletal muscle development, miRNAs are integral components of the regulatory circuitry for cardiac muscle development. Cardiac deletion of Dicer, the enzyme that cleaves pre-miRNAs to form mature miRNAs, results in embryonic lethality implying that miRNAs are essential for normal

heart development. miR-1, miR-133, and miR-208 are exclusively expressed in striated muscle, both skeletal muscle and heart. miR-206 is expressed in skeletal muscle and not in cardiac muscle. miR-1, a conserved miRNA ranging from fruit flies to humans, is expressed in striated muscle and is implicated in heart development. miR-1 and miR-133 are both expressed in the heart and are generated from a common bicistronic transcript.

There is an intricate relationship between miRNAs and transcription factors. miRNA expression is regulated by transcription factors. For example, the miR-1/133a locus is regulated by SRF and MEF2. These are the transcription factors that activate genes involved in muscle development and function, highlighting the integration of miRNA and mRNA regulatory networks.

Both miR-1 and miR-133 control cardiac fate; however, they have different target mRNAs and exert antagonistic effects on differentiation of muscle lineages. miR-1 promotes differentiation of embryonic stem cells toward a cardiac fate, whereas miR-133 inhibits differentiation into cardiac muscle. Overexpression of miR-1 in embryonic cardiomyocytes results in decreased proliferation of cardiomyocytes, a phenotype that has been attributed to a decrease in the expression of Hand2, a transcription factor that promotes cardiomyocyte proliferation. Other functions have been attributed to miR-1 and miR-133a, such as regulation of apoptosis in cardiomyocytes; miR-1 and miR-133a have also been shown to have functions within the vertebrate cardiac conduction system. miR-1 also modulates numerous ion channels involved in cardiac conduction.

Cardiac contraction is dependent on myosin heavy chain (MHC) proteins which are located in the sarcomere. There is an intimate relationship between MHC and miRNAs. The three muscle-specific myosin genes, Myh6 (α -MHC), Myh7 (β -MHC), and Myh7b, encode a family of intronic miRNAs (miR-208a, miR-208b, and miR-499), called MyomiRs, which control muscle myosin content and remodeling, myofiber identity, and muscle performance. The functions of the MyomiRs in the human heart are still being examined. In addition to regulation of cardiomyocyte development and function, recent reports have revealed roles of miRNAs in vascular development. The cardiovascular-specific miRNAs, miR-143 and miR-145, play key roles in modulating vascular smooth muscle cells.

MiRNAs are not only required for normal heart development and function but also involved in cardiac remodeling and disease. Multiple studies have shown an expression profile of distinct stress-responsive miRNAs during cardiac hypertrophy and heart failure. In fact, it has been reported that expression of individual miRNAs causes or alleviates disease. These studies have led the way to the concept of pharmacological manipulations of miRNAs as therapeutic reagents. AntagomiRs are cholesterol-modified antisense oligonucleotides that can be delivered *in vivo* and have been shown to inhibit miRNAs. By contrast, miRNA mimics are oligonucleotides that contain a mature miRNA sequence and can function as miRNAs to repress endogenous target genes. Since miRNAs control numerous facets of cardiac biology (including myocyte growth and survival, contractility, energy metabolism, fibrosis, and angiogenesis), miRNA-based therapeutics represents a potentially powerful approach to treat cardiovascular and skeletal muscle diseases.

Regeneration, Repair, and Striated Muscle Stem Cells

Skeletal Muscle Stem Cells

Adult skeletal muscle has the ability to regenerate and repair after injury. This is primarily due to a resident muscle stem cell population, called satellite cells. During skeletal muscle development, a progenitor cell population that expresses Pax3 and Pax7 arises in the center of the somite. As myogenesis progresses, Pax3 expression is decreased and the progenitor cell population, which expresses Pax7, occupies a satellite position around myofibers. Each muscle contains a pool of resident muscle stem cells that can either differentiate into muscle fibers or remain as proliferating progenitors.

In adult skeletal muscle, satellite cells reside as quiescent cells located under the basal lamina of skeletal muscle fibers. Following muscle injury, satellite cells are activated, move outside of the basal lamina, co-express Pax7 and MyoD, and differentiate into proliferating myoblasts that also express Myf5. Subsequently, they decrease Pax7 expression, express myogenin, and fuse to form multinucleated myofibers to repair damaged skeletal muscle.

A fraction of the Pax7 and MyoD expressing myoblasts will lose MyoD, Myf5, and myogenin expression, and stop dividing. It is believed that these cells become quiescent satellite cells and self-renew the satellite cell population. This indicates that satellite cells repair damaged muscle and self-renew, thus establishing them as skeletal muscle stem cells.

As skeletal muscle throughout the body is not derived from the same cell population, the same holds true for the satellite cells. The progenitor cells expressing Pax3 and Pax7 in the central region of the somite (central dermomyotome) give rise to satellite cells of the trunk. By contrast, the limb muscle satellite cells derive from the Pax3-expressing muscle progenitor cells that migrate from another region of the somite (hypaxial dermomyotome).

MiRNAs are emerging as regulators of skeletal muscle stem cells. For example, miRNA-27b (miR-27b) is expressed during myogenesis in the myotome and in activated satellite cells of adult muscle and targets the 3'-UTR of Pax3 mRNA. Recent studies showed that overexpression of a miR-27b in the embryo leads to downregulation of Pax3, resulting in interference with progenitor cell migration and in premature myogenic differentiation. AntagomiRs of miR-27b allow for continued Pax3 expression leading to more proliferation and a delay in the onset of differentiation.

Cardiac Stem Cells

Unlike skeletal muscle, it was considered dogma that the heart did not have resident cells that divide. However, recently it has been shown that the heart does have a cardiac stem cell population. There are different pools of cardiac stem cells and they are classified by their surface markers (c-kit, Sca-1, Islet 1, etc.). These cells are believed to comprise about 2% of the total heart cells and contribute to a natural turnover of cardiomyocytes.

In response to injury, such as a heart attack (myocardial infarction), cardiac stem cells are activated to form myocytes, which can restore some dead tissue and can contribute to normalization of cardiac function. However, unlike satellite cells, cardiac cells cannot fully repair the damaged heart and provide only a partial regenerative response.

The epicardium, the outermost surface of the heart, is another source of adult cardiac progenitor cells. It plays a role in the formation of the coronary vasculature during development and retains a regenerative potential in the adult. Understanding the transcription factors and miRNAs that regulate cardiac stem cells is under intense investigation. This information is key to the goal of using patient-specific cardiac stem cell therapy to regenerate and repair an injured heart with the intention of combating heart disease.

Conclusion

As highlighted in this article, skeletal and cardiac muscles use different evolutionarily conserved networks of transcription factors and miRNAs to regulate the programs controlling cell differentiation and morphogenesis during development. Due to the evolutionary conservation across diverse organisms, many of the regulatory processes were identified in a variety of organisms ranging from fruit flies to humans. Continued integration and collaboration among developmental and molecular biologists will reveal additional genetic networks involved in striated muscle development. These new discoveries will not only provide new insights into the general principles of organogenesis but also provide new approaches to facilitate therapies for cardiac and skeletal muscle diseases.

Glossary

Leucine zipper An amphoteric α -helical protein motif that includes several leucines on the hydrophobic surface that mediates coiled-coil protein dimerization.

Stem cell A cell capable of symmetric divisions giving rise to two additional stem cells or of asymmetric divisions giving rise to a new stem cell and a more committed progenitor.

Transcription factor A protein that binds to DNA in order to activate or repress gene expression.

Zinc finger A protein motif that complexes zinc ion via cysteine and histidine residues to form a structure that mediates DNA binding when present within transcription factors.

Developmental Hematopoiesis

Hematopoietic cells develop from the mesodermal germ layer, with embryonic hematopoiesis beginning in close association with endothelial cells within blood islands in the yolk sac. A primitive hemangioblast gives rise to endothelial cells and primitive hematopoietic progenitors at this early stage of development. Additional blood vessels throughout the embryo develop from a separate mesodermally derived angioblast. Embryonic hemoglobin predominates in primitive erythrocytes, which retain their nuclei. Primitive macrophages and neutrophils also develop, but the presence of pluripotent hematopoietic stem cells (HSCs) capable of giving rise to all the adult hematopoietic and lymphoid lineages awaits the development of definitive hematopoiesis. As development proceeds, a second wave of hematopoiesis initiates from a specialized hemogenic endothelium in the dorsal aorta within the aorta–gonad–mesonephros region of the embryo and in placental vessels. Both the transcription factors SCL, a member of the basic region helix–loop–helix or bHLH family, and GATA-2, a zinc finger protein, are required for the emergence of primitive hemangioblasts. SCL is also required for the formation of definitive hemogenic endothelium, and the transcription factor RUNX1 is required for subsequent emergence of HSC (Figure 1). Multiple endothelial promoters are regulated by cooperation between the FoxoC2 and ETV2, Ets family members, suggesting that these factors direct the endothelial fate of hemangioblasts or angioblasts. HSCs initially populate the fetal liver and ultimately the bone marrow. Red cells derived from HSCs lack nuclei, initially express fetal hemoglobin, and ultimately express adult hemoglobin consisting of α - and β -globin chains.

Hematopoietic Stem Cells

A diagram depicting key regulators required for development of adult hematopoietic lineages from the HSC is shown in Figure 2. Neither SCL nor GATA-2 is required for maintenance of HSC. In contrast, the absence of either TEL, an Ets family member, or the c-Myb or MLL transcription factors leads to a marked defect in HSC activity, whereas the absence of C/EBP α ,

a basic-region leucine zipper transcription factor, leads to HSC expansion, reflecting the ability of C/EBP α to inhibit cell cycle progression. At any given time, most HSCs remain in a quiescent state in marrow osteoblast or endothelial niches and enter cell cycle as needed throughout life to provide mature blood elements. As with all true stem cells, HSCs are capable of giving rise either to additional HSCs or to mature blood progenitors. Two key mediators of an early developmental decision made by HSCs are GATA-1, a zinc finger transcription factor, and PU.1, an Ets family protein. GATA-1 specifies formation of the megakaryocyte–erythroid progenitor (MEP), while PU.1 directs formation of the lymphoid–myeloid progenitor (LMP). GATA-1 and PU.1 each activate their own promoters to provide positive feedback for lineage specification, and GATA-1 and PU.1 antagonize each other's activities via direct protein interaction to prevent reversal of one or the other developmental decision.

Erythropoiesis and Megakaryopoiesis

The MEP commits to the erythroid lineage under the direction of GATA-1 in combination with EKLF, a zinc-finger protein, with additional contributions from SCL and NF-E2, a bZIP factor. Alternatively, MEPs give rise to the megakaryocyte lineage, directed by RUNX1 and members of the Ets family, including Fli-1 and ERG. GATA-ETS composite DNA elements help regulate several megakaryocytic genes. Of note, RUNX1 is absent from the erythroid lineage within hematopoiesis and directly interacts with GATA-1 to also induce megakaryocytic genes. FOG-1 is a transcriptional coregulator that cooperates with GATA-1 to activate erythroid genes and to repress megakaryocytic genes during erythropoiesis, while having the opposite effect on these genes during megakaryopoiesis.

Lymphopoiesis

The LMP gives rise to a common lymphoid progenitor (CLP) under the direction of Ikaros, a zinc finger protein. The CLP further matures along the B-lymphoid lineage under the direction of EBF, E2A, Pax-5, and PU.1. EBF binds DNA via a novel

Figure 1 Diagram depicting transcription factors and the cellular pathways leading to development of adult hematopoietic stem cells. AGM, aorta-gonad-mesonephros; HSC, hematopoietic stem cell.

Figure 2 Diagram depicting transcription factors and the cellular pathways leading to development of the adult hematopoietic lineages. CLP, common lymphoid progenitor; GMP, granulocyte-monocyte progenitor; HSC, hematopoietic stem cell; LMP, lymphoid-myeloid progenitor; MEP, megakaryocyte-erythroid progenitor; NK cell, natural killer cell; VDR, vitamin D receptor.

zinc-binding motif, E2A is a bHLH protein, and Pax-5 contacts DNA via a paired-box homeodomain. Low levels of PU.1 are required for B-lymphoid development, whereas monocytic maturation requires increased PU.1 levels. The CLP also gives rise to the T-lymphoid lineage under direction of Notch-1 and GATA-3. Notch-1 simultaneously suppresses E2A activity to inhibit B-cell development. RUNX1 is also required for optimizing B- or T-lymphoid development. RUNX1 favors the formation of $CD4^+CD8^+$ cytotoxic T cells through repression of the gene encoding the Th-POK transcription factor as well as the CD4 gene, and RUNX1 favors formation of $CD4^+CD25^+$ regulatory T cells through induction of FoxP3. Deletion of FLT3, a receptor tyrosine kinase, disrupts B lymphopoiesis in murine models, indicating a role for specific receptor signals in specification of this lineage. Natural killer cells and lymphoid dendritic cells also trace their origins to the CLP, dependent on expression of Id2, an antagonist of bHLH proteins such as E2A.

Monopoiesis and Granulopoiesis

The LMP gives rise to the granulocyte-monocyte progenitor (GMP) under direction of C/EBP α , and C/EBP α simultaneously suppresses lymphoid commitment through inhibition of Pax-5 and Notch-1 activities. C/EBP α induces PU.1 gene transcription to provide the increased levels required for monocyte lineage development. C/EBP α also forms complexes with c-Jun or c-Fos via their leucine zipper domains to generate heterodimeric complexes that favor monopoiesis. In contrast, C/EBP α homodimers may favor granulopoiesis. The zinc finger protein Gfi-1 helps direct granulopoiesis, and cross-inhibition between Gfi-1 and Egr-1 fixes monocyte versus granulocyte lineage specification. Retinoic acid receptor α (RAR α) complexes with RXR to help direct granulopoiesis, whereas vitamin D receptor binds RXR to contribute to monopoiesis. C/EBP β can assist C/EBP α during stress granulopoiesis and cooperates with nuclear factor

kappa B (NF- κ B) in mature monocytes/macrophages to direct expression of inflammatory mediators, and NF- κ B also contributes to the formation of monocytic and granulocytic progenitors. A third C/EBP protein, C/EBP ϵ , directs terminal phases of granulopoiesis. A micro-RNA, miR-223, is induced by C/EBP α to contribute to granulopoiesis via down-modulation of NFI-A. G-CSF activates STAT3 and the SHP2 tyrosine phosphatase, whereas M-CSF specifically activates PLC- γ and induces increased ERK activation, and small molecule inhibition of SHP2 impedes granulopoiesis, whereas inhibition of ERK reduces monopoiesis *in vitro*, suggesting a role for cytokine signal transduction in myeloid lineage specification. Immature monocytes give rise to mature macrophages, or alternatively to osteoclasts in response to M-CSF and RANKL or myeloid dendritic cells in response to IL-4 and GM-CSF.

Eosinophils, Basophils, and Mast Cells

The GMP also gives rise to eosinophils, basophils, and mast cells, dependent upon the order of transcription factor expression. When GATA-2 increases in GMP expressing C/EBP α , commitment to the eosinophil lineage occurs. Expression of GATA-2 combined with reduction of C/EBP α generates basophil/mast cell progenitors, and a subsequent increase in C/EBP α produces basophils, whereas further reduction of C/EBP α generates mast cells.

Glossary

Hedgehog ligands Proteins, such as Indian hedgehog and Sonic hedgehog, whose transient production is necessary for normal liver regeneration and survival but whose prolonged production promotes cirrhosis and neoplasia.

Hedgehog pathway Morphogenic signaling pathway that orchestrates tissue construction during fetal development and is silenced during hepatocyte differentiation and in healthy adult liver, but it is required for normal adult liver regeneration after chronic epithelial injury.

Hepatic steatosis Transient accumulation of lipids within hepatocytes that occurs during liver regeneration as a result of discrete alterations in the oxidation, transport mechanisms, and signaling pathways of fatty acids.

Liver regeneration Highly orchestrated process involving multiple intra- and intercellular pathways and signals that reconstructs the entire adult liver to restore optimal tissue-specific functions.

Liver regeneration phases An artificial temporal classification of related cellular and regulatory events required to accomplish liver regeneration. Acquisition of replicative competence of cells and extracellular matrix degradation occur in the priming phase; expansion of the cell population occurs in the proliferation phase; and cell growth is suppressed and extracellular matrix synthesized to terminate regeneration at a set point.

Matrix remodeling Sequential degradation and formation of extracellular matrix components to restore cell-to-matrix relationships among the various liver cell populations.

Stromal cells Stellate cells, endothelial cells, and immune cells, such as specialized macrophages and lymphocytes, that accompany epithelial cells (hepatocytes and cholangiocytes) in the liver and that need to be replaced in order to restore normal liver function.

Stromal elements Stromal cells, vasculature, and biliary conduits that support the viability and function of mature hepatocytes and cholangiocytes.

Introduction

Liver regeneration describes the process that reconstructs damaged adult liver to restore optimal tissue-specific functions. Adult livers become damaged as a result of normal day-to-day wear and tear, as well as by superimposed stresses imposed by various insults, such as trauma, exposure to endogenous or environmental toxins, infectious agents and/or immune system-mediated attack, disturbed perfusion, and processes that obstruct bile flow. Most of the research about liver regeneration has focused on mechanisms that regulate the proliferative activity of mature hepatocytes after 70% partial hepatectomy (PH). However, it is important to recognize that successful regeneration requires much more than the mere replacement of one type of liver epithelial cell (i.e., hepatocytes), because the healthy adult liver comprises multiple cell types. In addition to mature liver epithelial cells (hepatocytes and cholangiocytes) and their progenitors, there are different types of stromal cells. The latter include hepatic stellate cells, endothelial cells, and various types of immune cells, such as macrophages and lymphocytes. Liver regeneration after PH requires replenishing all of these cells, and reestablishing normal cell-to-cell and cell-to-matrix relationships among various liver cell populations so that the tissue can resume its normal biosynthetic, metabolic, and excretory functions. Given that the goal of liver regeneration is to reconstruct the healthy tissue, a brief review of normal hepatic morphology is justified.

Healthy Adult Liver Architecture

The adult liver is configured to optimize exposure of hepatocytes to blood and to provide efficient egress of lipid-soluble products from hepatocytes into the biliary tree for eventual delivery into the intestinal lumen. Unlike other organs, the liver has two sources of afferent blood supply, which are carried into the hilum of the organ via the portal vein and hepatic artery. Each of these vessels arborizes to give rise to progressively smaller branches that terminate in multiple small portal triads, which also house small intralobular branches of the biliary tree. From these portal triads, portal venous and hepatic arterial blood flows into a network of sinusoids that are lined by fenestrated endothelial cells. Only a small space (dubbed the space of Disse) separates the sinusoidal endothelial cells from the basal surfaces of the hepatocytes that are oriented along the sinusoids because neither the fenestrated endothelia nor the hepatocytes elaborate a typical basement membrane. The sinusoids gradually coalesce into larger vessels that become the terminal branches of the hepatic vein, which drains venous blood from the liver into the inferior vena cava. Thus, blood flows from portal triads toward terminal hepatic venules, bathing hepatocytes in factors derived from both the systemic and the mesenteric circulations. Bile flows in the opposite direction within bile canaliculi that are lined by the apical membranes of hepatocytes. Bile originates from hepatocytes that rim terminal hepatic venules and becomes progressively enriched with products that are released from the apical domains of hepatocytes that are closer to the

portal triads. As bile canaliculi approach the portal triads, their lumens become lined by cholangiocytes that form the intralobular bile ducts.

Although hepatocytes are large, and, thus, the most conspicuous cell type that lines hepatic sinusoids, other cells also localize in these areas. Hepatic stellate cells (which store retinoids and other lipids) reside in the space of Disse and the sinusoids themselves are enriched with various types of immune cells, particularly hepatic macrophages (dubbed Kupffer cells) and natural killer T cells (NKT cells; specialized T lymphocytes that respond to glycolipid antigens that are presented by CD1 molecules on the surfaces of other resident liver cells). Precursors of hepatic immune cells (Kupffer cells and lymphocytes) and sinusoidal endothelial cells are presumed to be recruited to the liver from extrahepatic sources (e.g., bone marrow and lymphoid tissues), and then to differentiate *in situ*, generating replacement cells for immune and endothelial cells that turnover during both health and disease states. The origin of replacement hepatic stellate cells in adult livers is unknown (see below) (Figure 1).

The portal tracts (which harbor the intralobular branches of the portal vein, hepatic artery, and the bile duct) also include the cells and stroma that comprise the walls of these conduits. Hence, portal tracts are enriched with fibroblastic cells, smooth muscle cells, and fibrous matrix. In addition, they contain occasional neurons and glial cells that form the peri-vascular and peri-ductular neural plexus. The portal regions are also enriched with progenitor populations for the liver epithelial compartments, including bipotent progenitors that are capable of differentiating into either hepatocytes or cholangiocytes.

Some of these progenitors are oriented along the bile canaliculi nearest portal triads (dubbed canals of Hering). Finally, the entire external surface of the liver is encapsulated in a serosal lining that is comprised of mesothelial cells and associated stromal elements.

Recent studies of developing fetal livers suggest that cells that reside immediately beneath the liver capsule may be precursors of hepatic stellate cells in developing livers. However, it remains to be determined whether or not stellate cells originate from subcapsular progenitors in adult livers. Adult stellate cell populations, themselves, exhibit considerable phenotypic plasticity, expressing stem/progenitor, neural, and adipocyte markers when quiescent, and efficiently transitioning into myofibroblastic cells during many types of liver injury. In addition, cultured stellate cells can be induced to express markers of other liver cell types, including endothelial cells, cholangiocytes, and hepatocytes. These findings have prompted speculation that stellate cells may be capable of functioning as multipotent progenitors under certain circumstances. At present, however, definitive proof of this concept is lacking. In any case, it is evident that healthy adult livers comprise multiple different types of cells (including progenitors), that many of these cells retain considerable phenotypic plasticity, and that different cell types interact to maintain the normal structure and function of the liver.

Liver Regeneration after PH

Resection of 70% of healthy adult liver (PH) triggers regenerative mechanisms that result in complete restoration of liver

Figure 1 The cellular complexity of the liver. Two major epithelial cell types constitute the liver: hepatocytes and cholangiocytes. Some liver diseases significantly impair the ability of hepatocytes to replenish the organ, and liver progenitor cells become activated. From the periportal zone of the liver (zone 1), liver progenitor cells or oval cells, due to their oval shape nucleus, proliferate, infiltrate along the liver plate, and differentiate into hepatocytes and cholangiocytes to restore liver function and mass. Bile canaliculi are connected with bile ducts through the canal of Hering, which is the niche of the liver progenitor cells. Kupffer cells, endothelial cells, stellate cells, and myofibroblastic cells are also resident liver cells.

mass and function within a week or so in adult mice and rats, and within months in adult humans. Although this process involves hyperplasia of residual mature hepatocytes, other cell types that were removed during the resection must also be replaced in order to restore the flow of blood and bile within the mass of newly formed hepatocytes. Without the latter, full recovery of liver-specific metabolic, biosynthetic, and detoxification functions would not be possible. Therefore, liver regeneration after PH requires reconstruction of stromal elements (e.g., hepatic stellate cells and resident immune cells), vasculature, and biliary conduits that support the viability and function of mature hepatocytes. Unfortunately, however, unlike mechanisms regulating hepatocyte proliferation (which have been extensively researched), mechanisms for replacing other types of liver cells and for reestablishing appropriate cell–cell interactions among various liver cell populations after PH have not been studied much and, thus, are poorly understood. We postulated that regeneration of the adult liver after PH might recapitulate certain aspects of fetal liver development because both situations require global construction of a complex tissue. Before discussing evidence for and against the concept that adult liver regeneration recapitulates fetal development, a brief review of pertinent aspects of fetal liver development is necessary.

Liver Morphogenesis during Fetal Development

During embryogenesis, the liver bud is formed via a process that requires paracrine signaling and cell migration between the developing heart (mesoderm), septum transversum mesenchyme (mesoderm and ectoderm), and the ventral endoderm. This occurs between days E8.5 and E9.5 in mice. Bone-marrow-derived cells subsequently infiltrate the liver bud and provide signals that are critical for further growth of the developing liver. Hence, liver morphogenesis involves movement of, and interactions among, cells that originated in the mesoderm, ectoderm, and the endoderm. A detailed review of the signaling mechanisms that orchestrate this process is beyond the scope of this article, but they are beautifully summarized elsewhere.

Suffice it to say that work in fetal explants showed that fibroblast growth factors (FGFs) and bone morphogenetic proteins (BMPs) released from the developing heart field are required for hepatic specification of the ventral endoderm. Further, it was demonstrated that hepatic specification was accompanied by induction of Sonic hedgehog (Shh) expression in endodermal cells, and that the latter did not occur unless FGF was provided. Those studies, therefore, suggested that Hedgehog (Hh) pathway activation was among the earliest events that occurred during construction of the fetal liver. Due to the pleiotropic actions of the Hh pathway during development, and functional redundancies among different Hh ligands and Hh-regulated transcription factors, the precise role(s) of Hh signaling in hepatic morphogenesis has (have), however, been difficult to demonstrate. Nevertheless, the following data support a role for the Hh pathway in fetal liver morphogenesis. First, pluripotent embryonic stem cells, endoderm-committed multipotent progenitors, and some committed

hepatic progenitors from fetal livers produce and respond to Hh ligands. Second, FoxA1 and FoxA2 (transcription factors which have been proved to be essential for hepatic specification of endodermal progenitors) are Hh target genes. Third, Hh signaling promotes viability and growth of Hh-responsive fetal liver progenitors. Fourth, the Hh pathway is known to regulate growth and differentiation of endothelial progenitors, thymic-derived lymphocyte progenitors, and bone-marrow-derived hematopoietic progenitors (all of which infiltrate the developing liver bud at some point during fetal life). Such cells also generally produce Hh ligands. Fifth, activation of Hh signaling promotes migration in multiple types of Hh-responsive cells (Figure 2).

In summary, many of the cell types which migrate into and accumulate within the fetal liver are capable of producing and/or responding to Hh ligands, and these factors regulate important cell-fate decisions, as well as the net growth, of those Hh-responsive cell populations. It seems, however, that the Hh pathway is gradually repressed during hepatocyte differentiation, because mature hepatocytes in healthy adult livers neither produce, nor respond to, Hh ligands. Moreover, although many other types of resident cells in healthy adult livers are capable of producing and/or responding to Hh ligands, only rare cells in and around portal tracts exhibit appreciable Hh pathway activity in uninjured adult livers (see below). The mechanisms that silence Hh signaling during hepatocyte differentiation, as well as those that more generally repress Hh pathway activation in Hh-responsive populations of other resident liver cells, remain to be discovered.

Figure 2 Normal or fibrogenic repair of the liver. Unlike other organs, the liver is capable of efficiently reconstructing the entire tissue without scarring (i.e., regenerating) following acute resection of most of its mass. This suggests that adult livers may be particularly adept at reactivating, and appropriately modulating, morphogenic mechanisms that orchestrate tissue construction during fetal development. However, sometimes liver injury leads to progressive fibrosis and architectural distortion (i.e., cirrhosis), rather than effective regeneration. Whether repair results in regeneration or cirrhosis may depend upon the success with which developmental morphogenic mechanisms are reactivated and then repressed.

Reactivation of the Hh Pathway in Regenerating Livers after PH

Because many types of cells (not merely mature hepatocytes) must be replaced after PH, and, as mentioned above, most of these are derivatives of Hh-responsive progenitors, we examined the possibility that the Hh pathway might become reactivated in the remnant liver following PH. Healthy adult mice were subjected to PH and sacrificed at various time points ranging from 6 h to 10 days post-PH so that Hh pathway activity could be examined in whole liver and primary liver cells that were harvested from regenerating liver remnants. PH was followed by an immediate and sustained reduction in hepatic expression of Hh interacting protein (Hhip), a soluble inhibitor of Hh ligands, and sequential increases in messenger RNA (mRNA) and protein levels of the Hh ligands, Indian hedgehog (Ihh), and Shh. Subsequently, expression of the Hh-regulated transcription factors, Gli1 and Gli2, also increased, followed by significant upregulation of well-established Gli-target genes, such as soluble frizzled related peptide (sFrp)-1. These findings indicated that PH resulted in Hh pathway activation in regenerating livers.

Immunohistochemistry and cell isolation studies proved that the hepatocyte and bile duct populations became particularly enriched with Hh-responsive cells (i.e., cells that expressed Hh-regulated transcription factors) around the times when these cells were maximally proliferative following PH. Moreover, treating mice with cyclopamine, a specific inhibitor of Hh signal transduction, significantly inhibited normal post-PH increases in both hepatocyte and cholangiocyte proliferation. Cyclopamine treatment also dramatically reduced post-PH survival in mice during the initial 72h after PH. When regenerating hepatocytes that had been harvested from mice 24h after PH were treated *in vitro* with cyclopamine, Hh signaling and proliferation were also reduced, proving that Hh pathway activation directly contributed to increases in hepatocyte proliferation that normally follow PH. Given that healthy mature hepatocytes are not Hh-responsive, this finding was curious.

One potential explanation was that Hh pathway activation promoted the outgrowth of hepatic progenitors that quickly differentiated and then proliferated. This concept is contradictory to current dogma (which posits that post-PH liver regeneration results from replication of mature hepatocytes in the liver remnant), but supported by several lines of evidence from our recent studies. First, cyclopamine treatment also inhibited cholangiocyte proliferation following PH, and both hepatocytes and cholangiocytes are the progeny of bi-potent hepatic progenitors. Second, populations of regenerating hepatocytes that were harvested 24h after PH were found to be enriched with cells that expressed progenitor markers. Third, PH resulted in a striking upregulation of progenitor-associated gene expression in whole liver tissue, causing, for example, a 40-fold induction of Fn14 (a tumor necrosis factor (TNF) superfamily receptor that is said to specifically mark bi-potent hepatic progenitors in liver) and more than 160-fold induction of alpha-fetoprotein (AFP), a well-established marker of immature liver epithelial cells. Fourth, immunohistochemistry for several other progenitor markers confirmed that PH stimulated accumulation of liver progenitors in regenerating livers. Fifth,

cyclopamine treatment significantly inhibited normal post-PH induction of FGF-inducible 14-kDa protein (Fn14), AFP, and several other progenitor markers in mice. Sixth, it also virtually eliminated progenitor accumulation following PH as assessed by immunohistochemistry. Similar approaches were used to prove that Hh pathway activation also plays a significant role in stromal cell responses that follow PH, including transient expansion of myofibroblast populations and hepatic matrix remodeling. Together, these data support the concept that normal regenerative responses in adult livers involve transient reactivation of mechanisms, such as Hh, which are likely to regulate liver morphogenesis during fetal development.

Sustained Hh Pathway Activation during Repair of Chronic Liver Injury

Healthy adult livers typically respond to acute resection of large amounts of their mass (e.g., PH) by regenerating successfully. Paradoxically, however, repetitive insults that merely accelerate the rate of death in subpopulations of liver cells (e.g., mature hepatocytes and/or cholangiocytes) often lead to scarring and hepatic architectural distortion (i.e., cirrhosis). Differences in the outcomes of PH and chronic liver injury suggest that entirely different repair mechanisms may be involved. Surprisingly, however, there is definite evidence of Hh pathway reactivation in all types of chronic liver injuries that have been examined to date in either rodents or humans, including injury caused by toxins (alcoholic- and obesity-related (nonalcoholic) fatty liver diseases), biliary tract damage (due to mechanical biliary obstruction, autoimmune disorders such as primary biliary cirrhosis and sclerosing cholangitis, or congenital factors, including biliary atresia, Alagille syndrome, and progressive familial intrahepatic cholestasis), and infections (hepatitis B and hepatitis C). Increased Hh pathway activity has also been demonstrated in many primary hepatocellular carcinomas and cholangiocarcinomas (Figure 3).

Recent research has demonstrated that many types of adult liver cells are capable of producing Hh ligands, including hepatocytes, cholangiocytes, hepatic progenitors, hepatic stellate cells/myofibroblasts, liver endothelial cell and certain types of liver lymphocytes (e.g., natural killer T cells NKT cells). Stimuli for Hh ligand production have been identified, and include growth regulatory cytokines (e.g., epidermal growth factor, platelet-derived growth factor, and transforming growth factor beta (TGF- β)) and pro-apoptotic stress (e.g., disruption of nuclear factor kappa beta signaling). The common downstream mediator of both types of ligand-inducing stimuli may be the phosphoinositide 3-kinase (PI3K)/AKT pathway, because direct adenovirally mediated manipulation of AKT activity alters Hh ligand production. It has also been demonstrated that ligand-producing liver cells release biologically active Hh ligands in membrane particles that have features of exosomes. Moreover, Hh-containing exosomes have been purified from the plasma and bile of rats with liver injury due to chronic biliary obstruction. Thus, although additional research is needed to clarify the molecular mechanisms controlling liver cell production and release of Hh ligands, current knowledge provides a plausible explanation that may

Figure 3 Reconstitution of the organ after liver injury or tissue loss involves replacement of target cells, and complex remodeling processes resulting in tissue architecture reconstruction. Hepatocytes are not terminally differentiated cells, but cells situated in the G_0 phase that can undergo proliferation upon appropriate stimulation. Hepatic stem cells and the other liver cells seem to be involved in this response. Hepatocyte proliferation is accomplished by a sequence of three phases: initiation, rendering cells in a state of replicative competence; proliferation, where expansion of the cell population occurs; and a termination phase, where cell growth is suppressed. Liver regeneration is regulated by ordered action of a plethora of transcription factors, growth factors, and cytokines, the significance of which has partly been defined by the use of animal models with target gene deletions. Hepatocyte regeneration is accompanied by a complex matrix remodeling, with a transient breakdown of the lobular architecture. Much less is known of the regenerative replacement of bile ducts, blood vessels, and hepatic stellate cells.

account for differences in the outcomes of acute PH and chronic liver injury. PH provides a temporally circumscribed stimulus for Hh ligand production, while the repetitive death of mature liver epithelial cells during chronic liver injury continuously drives Hh ligand production, resulting in sustained induction of Hh signaling in Hh-responsive cells.

Indeed, interrogation of chronically injured livers has revealed that many types of liver cells are capable of responding to Hh ligands, including immature hepatocytes, cholangiocytes, hepatic progenitors, myofibroblastic hepatic stellate cells, activated liver endothelial cells, and NKT cells. Hh ligands exert important effects on the fate of such Hh-responsive cells. For example, Hh pathway activation enhances the viability and growth of cholangiocytes, hepatic progenitors, myofibroblastic hepatic stellate cells, and NKT cells. It also activates liver sinusoidal endothelial cells and upregulates cholangiocyte production of chemokines for immune cells (monocyte/macrophages, fibrocytes, neutrophils, and B and T lymphocytes, including NKT cells). In cholangiocyte and hepatic stellate cell populations, induction of Hh signaling promotes cells to acquire a more mesenchymal, migratory phenotype. This process is mediated via Hh-dependent induction of several factors (e.g., bone morphogenetic protein-7, inhibitor of differentiation-2, and snail) that promote epithelial-to-mesenchymal transitions by repressing expression of E-cadherin and other junctional complex components. Hh pathway activation also stimulates NKT cells to express fibrogenic cytokines, such as interleukins 4 and 13. Thus, the net outcomes of protracted Hh signaling in chronically injured livers include virtually all of the responses that are known to occur during the pathogenesis of liver cirrhosis, including

fibrogenesis, inflammatory cell accumulation, vascular remodeling, and the outgrowth of liver progenitor populations that may harbor cancer stem cells for primary liver cancers.

The concept that both liver cirrhosis and carcinogenesis result from overactivation of conserved signaling pathways that are necessary for fetal liver development and adult liver regeneration is somewhat heretical, but supported by several lines of experimental evidence. First, both Hh pathway activation and increased fibrogenesis generally precede the emergence of cirrhosis and liver cancer by months to years in mice and humans with chronic liver injury. Second, the level of Hh pathway activity in injured livers tightly parallels the severity of liver fibrosis in rodents and humans, with the greatest accumulation of Hh-responsive cells occurring in cirrhosis. Third, cirrhosis is the single greatest risk factor for primary liver cancer in humans. Fourth, the capsules of human hepatocellular carcinomas are enriched with Hh-responsive cells that express markers of cancer stem/progenitor cells, and Hh-responsive cells are scattered throughout the stroma of primary liver cancers. Fifth, Hh signaling antagonists inhibit the growth of cultured liver myofibroblasts and liver cancer cell lines. Sixth, therapeutic interventions that successfully interrupt liver injury are accompanied by progressive downregulation of Hh signaling and regression of liver fibrosis, with eventual silencing of Hh pathway activity once healthy liver architecture has been recovered. Seventh, transgenic mice that are unable to efficiently silence Hh signaling after Hh pathway activation exhibit excessive liver fibrosis and expansion of hepatic progenitor populations when subjected to various liver injuries. These mice are also susceptible to spontaneous development of Hh-responsive malignancies. Work is being done in animal

models to determine if mice with ongoing liver injury survive long-term blockade of Hh signaling and, if so, whether or not this reduces subsequent liver fibrosis and cancer formation.

Summary

Recent evidence that transient activation of the Hh pathway is critical for normal liver regeneration and survival after PH complements other data which suggest that prolonged Hh pathway activation promotes cirrhosis and neoplasia. Together, these findings support the hypothesis that successful (as opposed to dysmorphic/fibrotic) repair of adult liver injury recapitulates aspects of fetal liver development, and is likely to be determined by the balance of factors that promote induction versus silencing of Hh signaling. Indeed, in non-liver cell types, it has already been shown that the Hh pathway interacts with other morphogenic signaling mechanisms that are known to regulate liver development, growth, and repair, including Wnt and TGF- β . Moreover, significant roles for those other pathways in the pathogenesis of liver cancer and cirrhosis are widely accepted: excessive Wnt signaling is thought to promote hepatocarcinogenesis and dysregulated TGF- β signaling is believed to provide a major stimulus for liver cirrhosis. Therefore, further research is needed to clarify cell-autonomous and paracrine mechanisms that modulate the activities and interactions of developmental morphogens in adult livers. The resultant knowledge will likely advance the prevention and treatment of cirrhosis and liver cancer, two of the most dreaded consequences of chronic liver injury. In addition, it may help to explain why healthy adult livers retain the capacity for efficient regeneration, but other vital organs do not.

Glossary

Adult neural stem cells Self-renewing multipotent precursor cells that can generate new neurons, astrocytes, and oligodendrocytes of the adult nervous system.

Dentate gyrus A subregion of the hippocampal formation involved in learning and memory and one of the few sites of neurogenesis in the adult mammalian brain.

Neurogenesis Process of generating functional neurons from stem/progenitor cells. It includes individually

regulated stages of proliferation, fate specification, migration, morphogenesis, and synaptic integration.

Neurogenic niche Microenvironment surrounding stem cells and their progeny which contains a host of extrinsic factors regulating adult neurogenesis.

Subgranular zone Proliferative region that lies adjacent to the granule cell layer in the dentate gyrus and is the locus of neural stem cells and progenitors that give rise to adult born dentate granule neurons.

Introduction

Neurogenesis describes the multistage cellular developmental process that begins with the first step toward proliferation of multipotent neural stem cells and culminates in the integration of functional new neurons into the local circuitry. Historically considered to be a singular series of events that occurs exclusively during embryonic development, cumulative evidence over the past several decades has confirmed that neurogenesis is a constitutive process in the mammalian brain. New neurons are born and incorporated into the existing neuronal framework throughout the life span of all mammals examined. Although neurodevelopmental processes are recapitulated in the mature brain, there are important differences between embryonic and adult neurogenesis. These differences can be broadly categorized along two dimensions – spatial and temporal. At the systems level, adult neurogenesis is spatially restricted and observed primarily in discrete regions of the central nervous system – the subgranular zone (SGZ), giving rise to glutamatergic neurons in the dentate gyrus of the hippocampus and the subventricular zone (SVZ), giving rise to at least two types of interneurons and a small percentage of glutamatergic neurons in the olfactory bulb. At the cellular level, it is informative to delineate between cell-autonomous and non-cell-autonomous factors that regulate neurodevelopment. Local microenvironments, or the neurogenic niche, can significantly impact neurogenesis, both quantitatively and qualitatively. Environmental conditions vary profoundly from embryogenesis to the adult brain. In the adult brain, essentially all steps of neurogenesis are impacted by diffusible and activity-driven signaling molecules operating within a functionally mature network. Temporally, adult neurogenesis is protracted compared to embryonic neurogenesis – individual developmental processes take longer in the adult brain. Overarching temporal factors also play a role in distinguishing embryonic and adult neurogenesis in that expression levels of functionally relevant proteins are often dynamically regulated throughout life.

Neurodevelopment occurs over the lifetime of an individual organism, first in a global process that generates numerous

cell types comprising the mammalian nervous system, and then in a local and prolonged process that generates specific subsets of neurons. Biochemical mediators of neurogenesis are thus spatially and temporally regulated. In addition, each process that contributes to the trajectory of neurodevelopment is governed by its own biochemistry. In this article, we focus on the major biochemical pathways that are involved in different stages of neurogenesis, describing the influential factors within key functional groups broadly divided between extrinsic and intrinsic factors. The spatial restriction and temporal expansion of adult neurogenesis make it an ideal model system to investigate neurodevelopment as a whole. Here we describe the current knowledge regarding the molecular mechanisms underlying postnatal neurogenesis in the dentate gyrus of the hippocampus.

Stages of Neurogenesis

Neurogenesis consists of sequential stages that define the progress of newly born neurons from neural stem cells to synaptic integration (Figure 1). Using adult hippocampal neurogenesis as our prototype, we will discuss biochemical mediators with respect to five stages of neurogenesis. (1) Proliferation of putative neural stem cells that reside in the SGZ of the hippocampus giving rise to transient amplifying cells. The primary neural stem/progenitor cells are radial glial-like cells that express nestin, glial fibrillary acidic protein (GFAP), and sex-determining region Y (SRY)-box 2 (Sox2). (2) Differentiation of highly proliferative progenitors into immature neurons. Immunohistochemical markers distinguish at least four cell types during this differentiation stage based on sequential and overlapping expression of nestin, T-brain gene-2 (Tbr-2), and doublecortin (DCX). All are GFAP negative and the first two subtypes, chronologically, express nestin. The intermediate subtype expresses nestin and Tbr2, while the late-stage, proliferative neuroblasts that are poised to migrate are nestin negative, Tbr2 negative, and positive for both DCX and the polysialylated embryonic form of neural cell adhesion

Figure 1 Stages of neurogenesis in the adult dentate gyrus. Simplified schematic of the trajectory of neurodevelopment from the adult neural stem cell to functional integration within the hippocampal circuitry. Below are the stage-specific markers that can be used to birth date and identify newly born neurons with the hippocampus.

molecule (PSA-NCAM). (3) Migration of immature, but post-mitotic neurons, expressing dentate granule cell marker Prox-1 to the granule cell layer of the dentate gyrus. (4) Axonal and dendritic morphogenesis of immature neurons. At this stage, neurons begin to express calretinin and the neuron-specific neuronal marker (NeuN). (5) Synaptic integration of newly born neurons. Mature granule cells are marked by the expression of calbindin rather than calretinin and the complex structure of dendritic and axonal processes are established within the hippocampal network in this final stage of neurogenesis.

In addition to the stage-specific markers described above, thymidine analogs such as bromodeoxyuridine (BrdU) can be incorporated into dividing cells during the S phase of the cell cycle, thereby establishing a means of birth dating newly born neurons through immunohistochemical analysis. Similarly, Ki67 marks all active phases of the cell cycle and histological quantification of this protein can timestamp levels of proliferation in the postnatal brain. All of these markers can be used individually or in combination to delineate the temporal phases of neurogenesis and track the progress of neural development from initial division of neural stem cells to the stable integration and functional viability of adult-born neurons. Using these markers in conjunction with targeted genetic disruption and manipulation of endogenous protein levels, much progress has been made recently in identifying the critical factors that regulate different aspects of adult neurogenesis.

Extrinsic Factors

Developing neurons are highly influenced by the local environment, which is itself subject to a wide variety of dynamic factors that reflect both cyclic variation and acute perturbations in the systemic balance of the organism. Many exogenous factors influence the rate of neurogenesis and the survival and integration of newly born neurons. Generally, there is a profound correspondence between factors that promote neurogenesis and those that promote the overall health of the organism as a whole. Exercise, sleep, sex, environmental enrichment, and learning are all conducive to neurogenesis. Conversely, stress, drugs of abuse, aging, and depression decrease neurogenesis in the adult brain. Contextual factors, such as genetic background and sexually divergent response patterns, add to the complexity of the dynamic neurogenic milieu. For instance, stress-induced glucocorticoids have a sexually dimorphic effect on hippocampal neurogenesis wherein increased levels of corticosterone in male rodents decrease cell proliferation and survival, but have minimal effect in females.

Understanding how these factors work in a synergistic or competitive manner at the molecular level to regulate neuronal development in the adult brain is an important focus of current research. Little is currently known about the relative strength of extrinsic modulators and whether there is a hierarchical relationship between competing influences. For example, focal

trauma may exert a dominant effect on neurogenesis but in the normal environment, it is not well understood how dynamically regulated factors interact to determine the neurogenic capacity of the local niche – for example, the net effect of temporally coincident exercise (a positive regulator) and elevated stress levels (a negative regulator). In addition, how extrinsic signals are integrated within the receiving cell is less well understood both at the transduction cross-talk and epigenetic levels. Nonetheless, an important first step in understanding the complex environment has been the identification of key components that have a consistent effect on specific stages of neurogenesis, which are described below along with known interactions.

Growth Factors, Cytokines, and Neurotrophins

Given the canonical role of neurotrophic factors in regulating cellular development, it is not surprising that many of the secreted proteins in this class have a demonstrated impact on multiple neurogenic processes. Predominantly, growth-related factors appear to exert influence over the early stages of neurogenesis, specifically serving to enhance stem cell self-renewal, as well as proliferation and differentiation of neural progenitors. We will review in brief some of the most extensively studied factors in this group that have established roles in neurogenesis.

Insulin-like growth factor 1 (IGF1) acts through at least two pathways to stimulate proliferation, neuronal differentiation, morphogenic development, and survival of newly born cells. Primarily synthesized in the liver, serum IGF1 also operates in a paracrine/autocrine manner in the brain and indirect actions of IGF1 include promotion of angiogenesis, which enriches the neurogenic niche. Dose-dependent proliferative effects of IGF1 on cultured hippocampal neural progenitors require activation of the mitogen-activated protein kinase (MAPK) pathway. Ras/Raf/MAPK activation may itself be initiated through distinct mechanisms mediated by the IGF1 receptor (IGF1R) including Son of Sevenless (SOS) or G-protein activation, culminating in transcriptional regulation through nuclear translocation of phosphorylated extracellular signal-regulated kinase (ERK)-1. Operating through the phosphoinositide 3-kinase (PI3K)-AKT (also known as protein kinase B) pathway, IGF1 signaling mediates the exercise-induced increase in survival of newly born neurons via promotion of anabolic activity and glucose utilization, and the inhibition of glycogen synthase kinase 3 β (GSK3 β).

In cultures of hippocampal neural stem cells, fibroblast growth factor (FGF-2) has been shown to regulate all aspects of self-renewal. Acting through the ERK1/2 pathway, FGF-2 enhances proliferation and suppresses spontaneous differentiation. Through a separate mechanism, FGF-2 works to preserve the multipotency that is characteristic of neural stem cells via activation of the phospholipase C gamma 1 (PLC γ 1) pathway. Knockdown of PLC γ 1 function predisposes stem cells toward differentiation of glial phenotypes suggesting an endogenous role of FGF-2-mediated signaling in preserving the possibility of neuronal differentiation *in vivo*. *In vivo* studies have demonstrated a reduction in granule cell population numbers in FGF2-deficient mice and an increase in hippocampal cell number following exogenous administration of FGF-2.

A critical determinant of the qualitative impact of the extrinsic neurogenic environment is the proximal vasculature. Vascular endothelial growth factor (VEGF) is a potent regulator of angiogenesis but also has a direct proliferative effect on progenitors and may also be involved in survival of newborn cells directly. While VEGF is minimally important in maintaining basal levels of adult neurogenesis, it plays an essential role in the enhanced neurogenesis observed following exposure of adult rodents to an enriched environment. It is also critically involved in the increased proliferation of neurons in the SGZ following antidepressant treatment. Flk-1, a VEGF receptor tyrosine kinase, is expressed in both neural progenitors and epithelial cells in the hippocampus and is the likely substrate for the initiation of the VEGF signaling pathway, although the downstream effectors remain largely unknown.

Brain-derived neurotrophic factor (BDNF) exerts its role in later phases of adult neurogenesis. It has a clearly established role in mediating synaptic plasticity and has been implicated in numerous higher-order processes, including learning and memory. In the hippocampus, BDNF may promote the selective stabilization of synapses recruited through activity-dependent mechanisms that reflect the experience of the organism. Experiments with hippocampus-specific deletion of BDNF suggest that this factor primarily affects neuronal survival in basal conditions, with little effect on proliferation or neuronal differentiation. However, intact BDNF signaling appears to partly mediate exercise and environmental enrichment effects on proliferation and stimulation of dendritic development. Downstream pathways that mediate the effects of BDNF through its cognate receptor TrkB include the MAPK/ERK pathway and the PI3K pathway, demonstrating a mechanistic convergence with other neurotrophic factors.

The cytokines, ciliary neurotrophic factor (CNTF) and leukemia inhibitory factor (LIF), are associated with common signal-transducing components, gp130 and LIF receptor β (LIFR β), and were originally believed to have similar effects in enhancing proliferation of progenitor cells in the SGZ. Recent data using knockout mice have shown that a loss of function of CNTF results in a decrease in the available pool of neural stem cells and that the mechanism of action appears to be mediated through the janus kinase (JAK)/signal transducer and activator of transcription 3 (STAT3) pathway. Impaired CNTF function mostly affects proliferation of primary progenitor/stem cell and also leads to the reduction of the population of newly born neurons. Unlike FGF-2, CNTF biases differentiation toward glial phenotypes. Functionally, CNTF appears to have a similar effect on proliferation in the SVZ but likely has a minimal effect during embryonic neurodevelopment and indeed, expression of this cytokine is restricted to the postnatal brain. LIF knockout mice did not display a phenotype in analysis of stem cell self-renewal, proliferation, or number of newly born neurons. Evidence instead suggests that this cytokine may be preferentially involved in the enhancement of neurogenesis in response to injury or ischemia, particularly during the perinatal period, when there is an absence of CNTF expression.

Bone morphogenic proteins (BMPs) inhibit the proliferation of neural stem cells and their action is antagonized by the endogenous expression of Noggin. Overexpression of Noggin

in transgenic mice increases the number of GFAP-positive neural stem cells, indicating that a homeostatic balance in the proliferative capacity of the neural progenitors in the hippocampus is at least partially maintained through a BMP–Noggin interaction. BMP signaling is also decreased by exercise in mice and is another putative mechanism for exercise-induced enhancement of neurogenesis. These actions are likely mediated by Smad signaling, but MAPK inhibition may also be involved.

In the adult brain, the embryonic morphogen sonic hedgehog (Shh) has a sustained influence on the proliferation of neuronal progenitors. Patched (Ptc), the Shh receptor, is present in granule cells and neural progenitors in the adult dentate gyrus. Transcriptional regulation of Shh targets is at least partly mediated through the release of Ptc inhibition of its constitutively associated transmembrane protein, Smoothened (Smo), which in turn activates members of the Gli (glioma-associated oncogene) family of transcription factors.

Wingless-type MMTV integration site-3 (Wnt3) is expressed in the neurogenic niche of the adult hippocampus and regulates proliferation and neuronal differentiation. The canonical Wnt pathway involves inhibition of GSK3 β and a subsequent increase of cytoplasmic β -catenin which translocates to the nucleus to regulate transcription of target genes such as NeuroD1. Noncanonical pathways operate through the direct activation of Jun-N-terminal kinase (JNK), or protein kinase C (PKC) and calcium-calmodulin-dependent protein kinase (CaMK) II, via a rise in intracellular calcium. Secreted frizzled-related protein 3 (sFRP3), an endogenous inhibitor of Wnt, is highly expressed in the dentate gyrus of the adult hippocampus and may regulate adult neurogenesis.

Neurotransmitters

A classical inhibitory neurotransmitter, gamma aminobutyric acid (GABA), actually depolarizes newly born neurons, as opposed to the hyperpolarizing role it plays in mature neurons. Mechanistically, the effect of GABA signaling is, at least in part, determined by the relative expression of Na–K–Cl cotransporter isoform 1 (NKCC1) and K–Cl cotransporter 2 (KCC2) transporters. These transporters determine levels of intracellular chloride and are dynamically regulated over the course of neuronal maturation. Current evidence suggests that the transcription factor, cAMP response element-binding protein (CREB), is a downstream effector of depolarizing GABA. Glutamatergic effects on neurogenesis appear to be highly dynamic from early proliferative stages to terminal synaptic integration and depend critically on the expression of receptor subtypes during the various stages. Glutamate signaling plays a critical role in the activity-dependent promotion of cell survival and synaptic development, an effect that could be mediated in part through a glutamatergic-mediated enhancement of BDNF. Other neurotransmitters have been implicated in select stages of neurogenesis, although there is much left to learn about the mechanisms which determine the developmental response of neurons to these signaling molecules. For example, norepinephrine- β_3 receptor signaling appears to activate precursor and stem cells in the SGZ. Dopaminergic signaling appears to have an opposite effect in that depletion of dopamine inputs to the hippocampus activates stem/progenitor cells.

Intrinsic Factors

Ultimately, most extrinsic modulators of neurogenesis rely on intracellular signaling pathways, but there are also specific proteins and molecular complexes that have been shown to have a cell-autonomous role in regulating neurodevelopment. Protein expression levels that are intrinsically regulated can determine the capacity of the developing neuron to survive and integrate into the existing circuitry. In addition, the ability of a proliferating neuronal precursor or newly born neuron to respond to extrinsic cues can be influenced by the genetically determined integrity of key signaling pathways. Here we review the most prominent and highly convergent pathways that regulate neurogenesis, selectively illustrated in [Figure 2](#).

Scaffold Proteins and Cell-Autonomous Signaling Complexes

One of the most prominent scaffold proteins implicated in neurogenesis is disrupted-in-schizophrenia 1 (DISC1). Several recent studies have shown that DISC1 is at the core of a multifunctional signaling complex, which affects nearly every stage of neurogenesis in the adult brain. Through direct interaction, DISC1 inhibits GSK3 β , which in turn stabilizes β -catenin via suppression of phosphorylation. GSK3 β activation and β -catenin stabilization inhibit proliferation of neural progenitors. Therefore, DISC1 effectively acts to disinhibit this negative regulation of proliferation in the adult dentate gyrus. Loss of function of the DISC1 protein results in decreased proliferation through modulation of cell cycle exit, which can be rescued by targeted inhibition of GSK3 β . Emerging evidence suggests that activation of the GSK3 β / β -catenin is a highly convergent pathway mediating the downstream effects of several extrinsic modulators of neurogenesis, including the neurotrophic factors IGF1, VEGF, FGF, Wnt3, as well as circulating glucocorticoids. In adult neurogenesis, retroviral-mediated suppression of DISC1 confers several distinct phenotypes of accelerated growth and overextended migration, suggesting that the endogenous role of DISC1 is to constrain intermediate and late-stage neurodevelopment. A central mediator of the DISC1 effect on postnatal neurogenesis is the AKT-mammalian target of rapamycin (mTOR) signaling pathway. DISC1 directly inhibits KIAA1212 (also known as Girdin), an activator of the AKT-mTOR pathway. As the investigation has progressed into the mechanisms that underlie these phenotypes, it has become clear that two additional signaling pathways contribute to specific facets of this developmental hypertrophy. Migratory defects and the appearance of ectopic dendrites are regulated by a direct interaction between DISC1 and nude nuclear distribution gene E homolog-like 1 (NDEL1). Somatic hypertrophy and excessive arborization of dendrites are the result of a fasciculation and elongation protein zeta-1 (FEZ1)–DISC1 interaction. Downstream mediators of these complementary DISC1-dependent pathways, however, have yet to be described in full.

Transcriptional Regulation and Epigenetic Factors

Transcription factors can control expression of multiple genes and proteins and thus may exert a pervasive effect on intracellular signaling cascades and the neurogenic niche. One of the most

Figure 2 Extrinsic and intrinsic factors regulating adult neurogenesis in the dentate gyrus. Highly simplified schematic illustrating some of the convergent pathways and prominent molecular regulators of neurodevelopment – target transcriptional and epigenetic modulators are shown in the lower center of the diagram.

prominent regulators of transcription to be implicated in neurogenesis is CREB. Although recent data have called into question the proliferative effects of CREB activation in adult neurogenesis, the phosphorylated form of CREB clearly supports the survival and morphological development of newborn neurons. In another example of the integral interactions between many of these neurogenic factors, phosphorylation of CREB may be a crucial effector signal in transducing the GABA-mediated depolarizing driving force on neurodevelopment.

Recent data have suggested a novel mechanism underlying how transient activity can generate long-lasting effects on neurogenesis. In the adult hippocampus of mice, growth arrest and DNA damage inducible 45-beta (Gadd45b) can be induced by synchronous activation of local networks following electroconvulsive treatment (ECT), as well as by physiological patterns of activation following increased exercise on a running wheel. Gadd45b, in turn, was shown to be required for region-specific DNA methylation following ECT. Intriguingly, activity-induced, Gadd45b-dependent, targeted DNA methylation was observed in the regulatory regions of the established modulators of neurogenesis, *Bdnf* and *Fgf1b*. Knockout of Gadd45b markedly reduces activity-induced increase in progenitor proliferation and dendritic growth. These results suggest a sequence of events wherein transient activation of cells in the neurogenic microenvironment can lead to an epigenetic modification cascade resulting in the persistent secretion of specific niche factors.

Cell-Type Specific Factors

In the adult brain, neurogenesis is largely restricted to a few neuronal and glial populations within the hippocampus and olfactory bulb. During embryonic neurogenesis, however, the entire spectrum of neuronal phenotypes must be generated. Distinct neuronal populations are identified by a unique combination of factors, including morphology, structural integration within local circuitry, and chemical and electrical transmission properties. Very little is currently known about the signaling pathways that underlie differentiation of specific neuronal types during adult neurogenesis. In order to fully realize the potential of stem cell therapy in the treatment of neurodegenerative disease, it is clear that much work needs to be done to understand the molecular mechanisms responsible for the differentiation and growth of specific neuronal populations.

Conclusion

Despite the complexity of the numerous signaling pathways and interacting biochemical mediators outlined above, this is by no means an exhaustive account of the molecular regulation of neurogenesis. We have focused on the most influential functional groups at present, highlighting only the most prominent factors in each. However, there are likely many key

cellular and molecular processes that remain to be identified and many explanatory gaps yet to fill, such as, signal integration hierarchy. Importantly, there may be characteristic modulators of specific neurogenic stages that operate in either, or both, a cell-autonomous or nonautonomous fashion and that a functional categorization of critical factors may expedite our progress toward a more complete understanding of neurogenesis. As with any investigation of a complexly regulated process, the goal should be to develop a coherent and simplified working model that accounts for the current data and provides a comprehensive framework in which to interpret new findings and generate novel hypotheses. With neurogenesis, the potential clinical benefits that could arise from such a model are profound. Increasing our understanding of the mechanisms underlying this constitutive phenomenon represents one of the most promising avenues toward exploiting the potential of stem cells to prevent and reverse the devastating consequences of neural pathology arising from disease and injury.

Glossary

Ataxia A neurological condition characterized by severe lack of movement coordination. It is a nonspecific manifestation due to lesions in the brain regions involved in movement coordination such as the cerebellum and the vestibular system.

Blood–brain barrier (BBB) The layers of epithelial cells separating the brain parenchyma and the cerebrospinal fluid from the blood. The BBB results from tight junctions between endothelial cells forming the walls of the capillaries. Therefore, only molecules having specific carriers (glucose, vitamins, and salts) or lipid-soluble molecules (O_2 , CO_2 , alcohol, psychoactive drugs, etc.) may cross this barrier. The BBB is essential for the protection and homeostasis of neurons and glia.

Encephalopathy A global dysfunction of the brain and altered mental state. Encephalopathies can have many different causes such as metabolic stress (due to inhibition of enzymes necessary for energy metabolism, mitochondrial dysfunction, or liver failure), infectious agents (prions, bacteria, and viruses), and toxins (drugs and industrial chemicals).

Excitotoxicity A pathological process during which receptors for excitatory amino acid neurotransmitters, in particular the *N*-methyl-D-aspartic acid (NMDA)-type glutamate receptors, are stimulated above normal levels,

leading to increased entry of Ca^{2+} into neurons. Overstimulation of various Ca^{2+} -dependent processes may then lead to neuronal death. This occurs in ischemia, neurodegenerative diseases such as Alzheimer's and Parkinson's diseases, and Wernicke–Korsakoff syndrome.

Nutritional downshift When bacteria are transferred from a rich medium (optimal for growth) to a medium lacking one or several nutrient categories (phosphates, nitrogen, carbon, amino acids, etc.), they respond by producing signaling molecules (alarmones) redirecting the cell metabolism to cope with the induced starvation stress.

Polyneuritis or peripheral neuropathy A damage of the nerves of the peripheral nervous system caused by trauma (compression), metabolic illness (vitamin deficiencies and diabetes mellitus), genetic illness (Friedreich's ataxia and Charcot–Marie–Tooth syndrome), toxins (heavy metals), or inflammatory disease (Guillain–Barré syndrome). This generally translates into weakness of the limbs (legs and feet) and sensory modifications.

Ylide (or ylid) A molecule wearing opposite charges on adjacent atoms. The negative charge is always on a carbon and it is therefore a particular kind of carbanion. Ylides often appear as reactive intermediates in organic reactions.

Introduction

Thiamine (thiamin, vitamin B1), also formerly called aneurin (anti-neuritic factor), is a water-soluble vitamin of the B group. It is an indispensable molecule for intermediate metabolism in all life forms. This is mainly because its diphosphorylated derivative (thiamine pyrophosphate or diphosphate (ThDP); see Figure 1) is required as a cofactor for central metabolic reactions such as the oxidative decarboxylation of pyruvate or oxoglutarate – key steps in energy metabolism. Thiamine is synthesized in microorganisms and plants; however, animals, including humans, have to rely on exogenous dietary sources.

As can be expected from the fundamental role of ThDP in metabolism, thiamine deficiency in animals has very harmful consequences, especially on the nervous system. This is, in part, because nerve cells heavily rely on glucose oxidation for their energy needs, and also because thiamine absorption is rather slow in these cells.

In humans, chronic nutritional thiamine deficiency is responsible for beriberi, a disease causing polyneuritis and paralysis. Beriberi was a major health problem in East Asian countries until the beginning of the twentieth century, because the major food source there was polished rice, which contains

very little thiamine. Nowadays, the most common disease linked to thiamine deficiency is the Wernicke–Korsakoff syndrome, an encephalopathy generally associated with chronic alcoholism. In developed countries, Korsakoff's psychosis not only remains the third cause of dementia, but subclinical thiamine deficiency is probably more common than generally thought, especially in elderly people and patients with diabetes or acquired immune deficiency syndrome (AIDS).

Chemical Properties of Thiamine

The structure of thiamine (Figure 1) is quite unusual as it consists of a pyrimidine moiety (2-methyl-4-amino-pyrimidine) and a thiazolium moiety [5-(2-hydroxyethyl)-4-methylthiazolium] connected through a methylene bridge. The aromatic heterocycle thiazole is rarely found in biological molecules. In cells, the hydroxyethyl group is generally esterified to form phosphorylated derivatives, the most widespread being the cofactor ThDP.

Thiamine and its phosphorylated derivatives are very hydrophilic molecules: 1 g of thiamine chloride hydrochloride ($C_{12}H_{17}ClN_4OS \cdot HCl$, molecular mass $337.27 \text{ g mol}^{-1}$) dissolves in $\sim 1 \text{ ml}$ of water. Thiamine is poorly soluble in organic solvents, including ethanol. It is heat-labile and

Figure 1 Natural thiamine derivatives. AthTP, adenosine thiamine triphosphate; ThDP, thiamine diphosphate; ThMP, thiamine monophosphate; ThTP, thiamine triphosphate.

partially lost by cooking. Aqueous solutions are most stable between pH 2 and 4. At pH < 4, thiamine is dicationic, as the N-1' of the pyrimidine ring (but not the -NH_2) is protonated. In alkaline solution, thiamine is unstable: in the pH range 8–10, hydroxyl attack on C-2 of the thiazolium ring leads to the relatively slow formation of a pseudobase intermediate (compound II in Figure 2) and the subsequent fast opening of the thiazolium ring. This yields a thiolate form (III) that can lose a water molecule to form the so-called yellow form (IV).

Note that, even in relatively strong alkaline medium, the ylide carbanion (which plays a key role in catalysis by ThDP-dependent enzymes, see below) is never observed in aqueous solutions of thiamine, because the estimated pK_a of the CH in question is too high (in the range 14–20). Nonetheless, a relative lability of the C-2 proton is demonstrated by the observation that it can be rapidly exchanged with deuterium.

Thiamine Biosynthesis and Riboswitches

Thiamine biosynthesis occurs in prokaryotes, fungi, and plants through complex pathways. The thiazole and pyrimidine moieties are synthesized separately before assembling to form thiamine monophosphate (ThMP), which is either hydrolyzed to thiamine or phosphorylated to ThDP.

Thiamine-degrading enzymes (thiaminases) exist in many organisms. Thiaminase I (EC 2.5.1.2), a pyrimidine transferase, is present not only in microorganisms, but also in some higher multicellular eukaryotes such as fern, shellfish, and fish. Consumption of raw parts of these organisms by animals or man can lead to serious thiamine deficiency syndromes, such as cortical necrosis in ruminants and beriberi in humans. Thiaminase II (EC 3.5.99.2), a hydrolase, might not be involved in the breakdown of thiamine as previously thought, but rather in the hydrolysis of aminopyrimidine to hydroxypyrimidine, a building block for the biosynthesis of thiamine by some bacteria.

Thiamine biosynthesis is regulated by metabolite-sensing messenger RNAs (mRNAs), called 'riboswitches'. These small RNA molecules are part of an mRNA molecule, typically at the 5'-untranslated region, coding for a protein involved in a biosynthetic pathway. Riboswitches have been identified for vitamins, amino acids, and nucleotides. The binding of such small molecules leads to a change in the conformation of the mRNA, affecting protein expression. The ThDP riboswitch (Thi-box) is found in many bacteria, fungi, and plants, and is the most widespread riboswitch known today. It acts by various mechanisms. In *Escherichia coli*, ThDP binding to the Thi-box leads to the formation of a terminator hairpin, halting the transcription of several thiamine biosynthetic enzymes. In fungi and plants, the Thi-box is involved in the control of RNA splicing rather than transcription or translation. The ThDP riboswitch is the only one

so far described in eukaryotes. The existence of riboswitches, in addition to ribozymes, demonstrates that macromolecules other than proteins are able to bind small molecules with high specificity, supporting the RNA world hypothesis.

Determination of Thiamine Derivatives and Their Distribution in Various Living Organisms

Early methods for the determination of thiamine in biological or pharmaceutical preparations included paper, thin-layer, or liquid chromatography. Nowadays, mainly high-performance liquid chromatography (HPLC), after derivatization of thiamine compounds to the corresponding highly fluorescent thiochrome derivatives, is used because of its sensitivity, selectivity, and resolution (Figure 3). All thiochrome derivatives have approximately the same excitation optimum at 360 nm and the same emission maximum at 430–435 nm.

In most eukaryotic tissues, the cofactor ThDP is the most abundant thiamine compound. Free thiamine and ThMP generally amount to 5–15% of total thiamine, while ThTP, adenosine thiamine triphosphate (AThTP), and adenosine thiamine diphosphate (AThDP) are even less abundant (but exceptions exist, see below). In animal cells, such as neurons, ThDP is found in highest amounts in mitochondria, where it is mostly bound to pyruvate and oxoglutarate dehydrogenase complexes. Smaller amounts are found in the cytosol (partly free and partly bound to transketolase (TK)). In liver and skeletal muscle, however, ThDP is mostly cytosolic. ThDP is also present in peroxisomes, where it is bound to 2-hydroxyacyl-CoA ligase. The triphosphorylated derivatives ThTP and AThTP are generally minor compounds in animal tissues, but ThTP has been consistently found in most organisms, from bacteria to mammals. The subcellular distribution of ThTP in animal cells varies with the tissue studied. In rodent brain, it is essentially localized in mitochondria, while it is mainly cytoplasmic in skeletal muscle. These differences are probably related to different mechanisms of ThTP synthesis (see below). In *E. coli*, ThTP is not found under optimal growth conditions, but it can accumulate significantly (>20% of total thiamine) during amino acid starvation.

AThTP is found in several tissues (mammalian liver and heart, roots of higher plants, etc.), but it is not as widespread as ThTP. In *E. coli*, it is produced in response to carbon starvation. As to AThDP, it was only found in low amounts in rodent liver and in *E. coli*.

Thiamine Transport

Thiamine is found in most food, but whole grains, liver, and yeast are particularly rich sources. The Reference Daily Intake is 1.4 mg, but depends on carbohydrate intake. Large excess oral intake does not seem to have adverse effects. However, allergic reactions (anaphylactic shock) are a rare complication of intravenous thiamine administration.

Thiamine phosphate esters taken up from the food are hydrolyzed to thiamine in the small intestine, transported as thiamine or ThMP across the brush-border membrane to the portal system, and distributed to the various tissues. There is no true thiamine storage reservoir in the body, though, because of its size and high ThDP content, the liver contains 10–20% of total body thiamine. In case of reduced thiamine intake, it can be released from the liver and transported via the blood flow to other tissues (in particular the brain). Excess thiamine and some of its metabolites (2-methyl-4-amino-5-pyrimidine carboxylic acid and 4-methyl-thiazole-5-acetic acid) are excreted in the urine. Three kinds of cell membrane thiamine transporters have been described. They all belong to the *SLC19A* solute carrier gene family. *SLC19A1* encodes a reduced folate transporter that may also transport ThMP and ThDP, but not thiamine. THTR-1 (product of the *SLC19A2* gene) and hTHTR-2 (product of the *SLC19A3* gene) are thiamine/ H^+ antiporters, rather ubiquitously expressed in mammalian tissues.

Thiamine transport across cell membranes, particularly the blood–brain barrier, is a relatively slow process. Furthermore, plasma levels of thiamine are relatively low in humans as compared to other mammalian species. Both factors probably contribute to the fact that marginal thiamine deficiency is more common than initially thought of. In order to overcome severe deficiencies, several thiamine precursors (i.e., thiamine disulfides and benfotiamine) with a higher bioavailability were

developed. These molecules are generally lipophilic, easily crossing the membranes, and their administration results in a rapid and strong increase in plasma thiamine levels.

Metabolism of Thiamine Phosphates

Thiamine phosphate derivatives can be readily interconverted, but the enzymes involved in these reactions remain poorly characterized (Figure 4). Only two of them, the essential thiamine pyrophosphokinase and the 25-kDa thiamine triphosphatase, have been characterized at the molecular level.

Synthesis of ThDP

Thiamine taken up by cells is converted to ThDP by a ubiquitous cytosolic adenosine triphosphate (ATP): thiamine diphosphokinase or thiamine pyrophosphokinase (ThDPK or TPK; EC 2.7.6.2). The K_m for thiamine is in the low micromolar range, while the K_m for ATP is high ($\sim 10^{-2}$ M). The equilibrium of the reaction is not in favor of ThDP formation. Therefore, it must be shifted to the right, either by binding of ThDP to apoenzymes or through conversion of adenosine monophosphate (AMP) to adenosine diphosphate (ADP) by the adenylate kinase reaction (in muscle cytoplasm).

Synthesis of ThTP

The mechanism of ThTP synthesis and its physiological role are very controversial. The first mechanism proposed, a reaction catalyzed by a soluble ThDP-kinase: $ATP + ThDP \rightleftharpoons ADP + ThTP$, was never substantiated. ThTP can be synthesized by adenylate kinases (EC 2.7.4.3) according to the reaction $ADP + ThDP \rightleftharpoons AMP + ThTP$. The rate of reaction

is 10^6 – 10^7 times slower than the synthesis of ATP according to the reaction $2 \text{ ADP} \rightleftharpoons \text{AMP} + \text{ATP}$. Thus, synthesis of ThTP by this mechanism is significant only in tissues where adenylate kinase is very abundant, such as skeletal muscle, electric organs, or red blood cells. ThTP may be the predominant thiamine compound when the 25-kDa ThTPase is absent, such as in electric organs or chicken skeletal muscle. In brain mitochondria, ThTP is synthesized according to the reaction $\text{ThDP} + \text{P}_i \rightleftharpoons \text{ThTP}$, coupled to the respiratory chain through a chemiosmotic mechanism.

Synthesis of AThTP

AThTP can be synthesized by a soluble ThDP adenylyl transferase, according to the reaction $\text{ADP (ATP)} + \text{ThDP} \rightleftharpoons \text{P}_i (\text{PP}_i) + \text{AThTP}$. Although both ATP and ADP may be the phosphate donor for this reaction, ADP is probably more physiologic as AThTP is synthesized under conditions of energy stress in *E. coli*. This bacterial enzyme has been partially characterized.

Hydrolysis of ThDP and ThMP

Several phosphatases may hydrolyze ThDP, but until now no specific thiamine diphosphatase (ThDPase) or thiamine monophosphatase (ThMPase) has been characterized at the molecular level. ThDPases studied so far also hydrolyze nucleoside diphosphates. ThDPase activity has been used as a Golgi marker. ThMPase activity, a classical marker of small-diameter dorsal root ganglia neurons, is probably identical to the transmembrane isoform of prostatic acid phosphatase. This enzyme, in fact an ecto-5'-nucleotidase, hydrolyzes adenosine monophosphate to adenosine, which can then activate A_1 -adenosine receptors, suppressing pain.

Hydrolysis of ThTP

Membrane-associated and cytosolic thiamine triphosphatases (ThTPase; EC 3.6.1.28) have been described. The membrane-associated ThTPase could not be purified so far. In contrast, a soluble ThTPase, purified from mammalian tissues, has a nearly absolute specificity for ThTP. It is a 25-kDa protein with no homology with other known mammalian proteins. Its mRNA is widely expressed in human tissues, though at relatively low levels. Orthologs are found in nearly all animals, except birds.

Thiamine-Binding Proteins

Thiamine-binding proteins have been described in many animal and plant tissues, but none were characterized at the molecular level. They exist in eggs or plant seeds, probably as thiamine storage proteins.

Cofactor Role of ThDP

ThDP is an indispensable cofactor for energy metabolism in virtually all cell types. In animals, it is involved in several important enzyme reactions in both carbohydrate and amino

acid catabolism (Figure 5). TK (EC 2.2.1.1), a cytosolic enzyme, catalyzes a key step in the pentose phosphate pathway. In mitochondria, ThDP is required for the oxidative decarboxylation of pyruvate and 2-oxoglutarate. Pyruvate dehydrogenase (PDHC; EC 1.2.4.1) and oxoglutarate dehydrogenase (OGDHC; EC 1.2.4.2) complexes catalyze two essential steps of the Krebs cycle. ThDP is also required for the catabolism of branched-chain amino acids, being the coenzyme of branched-chain 2-oxo acid dehydrogenase (BCOAD; EC 1.2.4.4) in mitochondria. In peroxisomes, it is the coenzyme for 2-hydroxyacyl-CoA lyase (HACL1). In yeasts, ThDP is a cofactor for pyruvate decarboxylase (EC 4.1.1.1) catalyzing the anaerobic decarboxylation of pyruvate to acetaldehyde in alcoholic fermentation. ThDP is also the cofactor for several additional enzymes in plants and prokaryotes, such as acetolactate synthase (EC 4.1.3.18) or pyruvate oxidase (EC 1.2.3.3).

Catalytic Mechanism Involving Thiamine Diphosphate

ThDP acts as catalyst for the decarboxylation of 2-oxo acids (α -cleavage; eqn [1]) and the cleavage (or formation) of α -hydroxyketones (eqn [2])

There is no simple acid–base-catalyzed mechanism for such reactions, hence the need for a special coenzyme.

It is now well established that the first committed step in ThDP-dependent enzyme reactions is the deprotonation of the thiazolium C-2 and attack of the resulting carbanion on a substrate carbonyl. As evidenced by the easy exchange of the C-2 proton with deuterium, this CH group is more acidic than most $=\text{CH}-$ groups. Proton removal from C-2 is assisted by the adjacent positive charge ($=\text{N}^+$). In addition, the aminopyridinium moiety of ThDP, presumably involving the imino tautomer, acts as a general base. Finally, a strictly conserved glutamate residue of the apoenzyme forms a hydrogen bond with the weakly basic N-1' of the aminopyridinium, also facilitating the dissociation of the H^+ in C-2 position of the thiazolium.

As already suggested by Breslow over 50 years ago, the thiazolium dipolar ion (or ylide) formed by this dissociation is the key intermediate in all ThDP-dependent enzyme reactions. Note that the diphosphate group plays no role in catalysis and is only required for tight binding of ThDP to the apoenzymes. The anionic carbon of the thiazolium ring readily reacts with substrates by addition to the carbonyl group, forming a covalent adduct. As a typical example, we shall consider the mechanism of pyruvate decarboxylation that occurs as the first step in the conversion of pyruvate to acetyl-CoA by the PDH complex. This step is catalyzed by the E1 subunits. As

Figure 5 Enzyme reactions requiring ThDP as a cofactor in an animal cell. BCOAD, branched-chain 2-oxo acid dehydrogenase; HAC11, 2-hydroxyacyl-CoA lyase; OGDH, oxoglutarate dehydrogenase; PDH, pyruvate dehydrogenase; TK, transketolase.

shown in **Figure 6**, the first adduct formed is α -lactyl-ThDP. In this complex, the $=N^+$ group of the thiazolium acts as an electron sink to stabilize the formation of the negative charge, which is necessary for decarboxylation. After the release of CO_2 , the activated aldehyde attached to ThDP is oxidized to form an acetyl group and concomitantly transferred to lipoyl groups attached to the E2 subunits, while the ylide is regenerated (**Figure 6**).

One of best-studied ThDP-dependent enzymes is *E. coli* PDH. Its mechanism can be considered as the paradigm for the oxidative decarboxylation of 2-oxo acids. This multisubunit complex catalyzes the conversion of pyruvate to acetyl-CoA, which can then enter the Krebs cycle:

E. coli PDH is a large complex (~2390 kDa) composed of multiple copies of three distinct subunits: 24 subunits of PDH (E1, EC 1.2.4.1), 24 subunits of dihydrolipoyl S-acetyltransferase (E2, EC 2.3.1.12), and 12 subunits of dihydrolipoyl dehydrogenase (E3, EC 1.8.1.4). Five different coenzymes (ThDP, lipoic acid, coenzyme A, FAD, and NAD^+) are involved in the reaction catalyzed by the complex. ThDP is the cofactor for E1, the enzyme catalyzing the decarboxylation

of pyruvate, and the transfer of the acetyl moiety to the lipoyl cofactor attached of E2. The structure and mechanism of the OGDH complex are quite similar to those of the PDH complex.

ThDP is bound to a conserved amino acid sequence GDG-X₂₆-NN via a Mg^{2+} cation. This consensus sequence (ThDP-binding motif) is conserved in all ThDP-dependent enzymes.

Non-Cofactor Roles of Thiamine Derivatives

Non-cofactor roles of thiamine and its phosphate derivatives have been proposed for many years, following the work of Alexander von Murlalt in the 1930s and 1940s. This was based on the observation, made independently by several investigators, that electrical stimulation of isolated nerves led to release of thiamine. It was speculated that this release might result from a dephosphorylation shift of phosphorylated derivatives. This drove interest to ThTP that exists in small amounts in nervous tissues, and was sometimes considered as a neuroactive form of thiamine. However, interest in this compound rapidly faded, as early results were questioned, because reliable detection proved to be difficult. In the early 1980s, estimation of ThTP content in brain by HPLC showed that it was less abundant than previously thought, and an earlier hypothesis

Figure 6 Catalytic mechanism for the first step (pyruvate decarboxylation) of the reaction catalyzed by the PDH complex. Pyruvate decarboxylation is catalyzed by the E1 subunits of the complex that bind ThDP. AP, 4'-aminopyrimidinium IP, 1', 4'-iminopyrimidinium; ThDP, thiamine diphosphate; $R = C_2H_4OP_2O_6^{3-}$.

concerning its possible role in nerve excitation could not be substantiated. However, the discovery of the specific 25-kDa ThTPase with high catalytic efficiency in mammalian tissues, as well as the finding that ThTP can phosphorylate some proteins in brain and electric tissue still suggests that ThTP may play some physiological role in brain and other animal tissues. In *E. coli*, it was recently found that ThTP accumulates in large amounts in response to amino acid starvation, suggesting a specific role in the adaptation of bacteria to nutritional downshifts. The discovery of an adenylated thiamine triphosphate derivative (ATHTP or thiaminylated ATP; **Figure 1**) in 2007 came as a surprise. ATHTP accumulates in *E. coli* during carbon starvation. This compound, like ThTP, might thus be a kind of alarmone, involved in emergency signaling when the cells undergo some forms of metabolic stress. In eukaryotic organisms, the possible biological role(s) of triphosphorylated derivatives (ATHTP and ThTP) remains unknown.

Human Diseases Related to Thiamine Deficiency

Ill-equilibrated diet or problems in absorption can lead to thiamine deficiency. Humans appear to have relatively low plasma and cellular thiamine levels, and this may be the reason why humans are particularly sensitive to thiamine deficiency. Severe chronic or acute deficiency leads to two main diseases, beriberi and Wernicke–Korsakoff syndrome. However, in addition to these classical disorders, marginal thiamine deficiency is probably quite common, particularly in high-risk groups such as elderly

people, lactating women, diabetic, and AIDS patients. People with Alzheimer's disease also have lower cerebral ThDP levels and impaired 2-oxoglutarate dehydrogenase activity.

Beriberi

Beriberi is a polyneuritic syndrome, mainly affecting the lower limbs. Symptoms of dry beriberi include weakness and pain in the limbs, weight loss, and partial paralysis. In wet beriberi, there are also cardiovascular symptoms, including cardiac insufficiency and enlargement, with tendency to edema. A low TK activity of red cells is a reliable diagnostic indicator of severe thiamine deficiency. Beriberi is the classical manifestation of chronic dietary deficiency in vitamin B1. Before the discovery of thiamine, it was a major health problem in East Asian countries, where polished rice (thiamine is mainly present in the husk of rice) was the staple food.

Wernicke–Korsakoff Syndrome

Although severe dietary thiamine deficiency has become rare in Western countries, a special form of deficiency associated with chronic alcoholism remains frequent. This is related to the poor nutritional status of many alcoholics and also to the fact that alcohol interferes to some extent with thiamine absorption and its intracellular conversion to ThDP.

The acute manifestation of this disorder is Wernicke's encephalopathy, a state of confusion with neurological symptoms such as ophthalmoplegia, nystagmus, and ataxia. In the absence of

prompt therapy with high-dose thiamine, coma and death occur rapidly. In many cases, recovery will not be complete and irreversible sequelae, due to specific brain lesions, will be observed. These lesions often result in a state of dementia called Korsakoff's psychosis. This is an amnesic syndrome, most often including a loss of anterograde memory. This may be accompanied by confusion, apathy, disorientation, and fabrications. Surprisingly, the brain lesions are rather specific, mainly affecting thalamic nuclei and mammillary bodies, while (in contrast to Alzheimer's disease) the cortex is largely spared. Brain damage in Wernicke–Korsakoff syndrome is assumed to be related to impairment of oxidative energy metabolism, neuronal death arising from a combination of excitotoxicity, oxidative stress, and inflammatory processes (the latter may primarily affect endothelial cells of the microvessels rather than neurons). However, the reasons for the selective vulnerability of some brain regions remain elusive and are the subject of active investigation.

Defects in Thiamine Transport and in ThDP-Dependent Enzymes

Mutations in the genes coding thiamine transporters or ThDP-dependent enzymes may lead to specific diseases in humans.

Thiamine-Responsive Megaloblastic Anemia

Thiamine-responsive megaloblastic anemia is characterized by megaloblastic anemia, sensorineural hearing loss, and diabetes mellitus. It is caused by mutations in the THTR-1 high-affinity transporter. Relief of the symptoms is generally obtained by high-dose thiamine treatment.

Amish Lethal Microcephaly

The children affected by Amish lethal microcephaly are born with a very small head and an underdeveloped brain, and they do not live beyond six months. The disease results from a point mutation in the mitochondrial ThDP transporter gene *SLC25A19*, leading to its inability to transport the cofactor to the mitochondrial matrix. This causes the inactivation of PDH and OGDH complexes, and impairment of oxidative metabolism.

Leigh Disease (Subacute Necrotizing Encephalomyelopathy)

Leigh disease is a rare heterogeneous neurodegenerative disorder of early childhood, involving focal, symmetric necrotic brain lesions, leading to death generally before the age of five. It is clinically and genetically heterogeneous, presenting central and peripheral nervous system abnormalities that result from deficits in respiratory chain mitochondrial complexes (I, II, III, IV, and V) or PDH. In a small percentage of patients (<10%), high-dose thiamine may have beneficial effects.

Maple Syrup Urine Disease

Maple syrup disease (branched-chain ketoaciduria) is an autosomal recessive disorder caused by mutations in branched-chain 2-oxo acid dehydrogenase. The toxic effect is due to the accumulation of the branched-chain amino acids (leucine, isoleucine, and valine) and their 2-oxo acid degradation

products. If not treated by special diets, the patients will develop brain damage after birth, leading to death. High-dose thiamine therapy may be efficient, in particular when the E1 component of branched-chain 2-oxo acid dehydrogenase is affected.

Conclusion

It was long considered that the only reason for the existence of thiamine was to form the cofactor ThDP, an argument also based on the observation that thiazole, a heterocycle absolutely required for catalysis, is rarely observed in biological molecules. Although it remains true that the main functions of this vitamin are linked to catalysis by ThDP, the existence of triphosphorylated derivatives, such as ThTP and ATHTP, whose levels are highly specifically regulated, strongly suggest that these compounds play a biological role, at least in bacteria. Thiamine compounds form a family of molecules that, with respect to their degree of phosphorylation, is reminiscent of nucleotides (though thiamine, lacking a sugar moiety, is not a nucleotide). This suggests that in addition to the classical cofactor role of ThDP, some thiamine derivatives have non-cofactor roles.

Bioenergetics and the Mitochondrial Genome

D C Wallace, University of Pennsylvania, Philadelphia, PA, USA

© 2013 Elsevier Inc. All rights reserved.

It is becoming increasingly clear that our understanding the biology of the mitochondrion and the genetics of the mitochondrial genome will be central to our determining the genetic and pathophysiological basis of a wide variety of complex human diseases. This is because to be alive requires structure (anatomy), the flow of energy (the vital force), and the information necessary to maintain the anatomical and energetic systems of the body. While all of the information for the anatomy of humans and animals is encoded by the chromosomal and thus Mendelian-inherited nuclear DNA (nDNA), the most important elements of the energy-generating system, oxidative phosphorylation (OXPHOS), are encoded in the non-Mendelian mitochondrial DNA (mtDNA). Therefore, most human diseases will involve an interaction between anatomy and energy, and hence their genetics will involve a mixture of both Mendelian and non-Mendelian genes.

Mitochondrial Origin and Function

The mitochondria are symbiotic bacteria that reside within the cytoplasm of virtually all eukaryotic cells (cells with a nucleus). The mitochondrion originated when an α -Proteobacteria, a *Rickettsia*-like oxidative bacterium, formed a symbiotic relationship with the proto-nucleus-cytosol organism about 2–2.5 billion years ago. Hence, each human cell is composed of two life forms which were originally co-equal microorganisms. As the symbiosis matured, one organism became specialized in encoding structural information and gave rise to the nucleus-cytosol of the modern human cell. The other became specialized in energy production and gave rise to the modern mitochondrion. As this functional specialization matured over the first 1.2 billion years, the proto-mitochondrion gave up all of its genomic information for maintaining its structure to the proto-nucleus-cytosolic organism, ultimately surrendering more than 99% of its genome. However, the mtDNA retained the core information for the electrical components of OXPHOS, literally the wiring diagram of the mitochondrial power plants.

From its origins up to the present day, virtually all energy flux through the eukaryotic cell goes through the mitochondria and is controlled by the mtDNA. With the advent of multicellularity, ever-increasing cellular and later multicellular structural complexities were elaborated resulting in the continual addition of new anatomical information to the nDNA. Since considerable energy is required to replicate, transcribe, and translate genes, as the number of nDNA genes increased in the cell, the number of mitochondria per cell also needed to increase to provide the requisite energy. Today the human cell has a massive nucleus encompassing two copies of approximately 23000 genes. To generate sufficient energy for these genes, the human cell generally requires hundreds of mitochondria and thousands of mtDNAs.

The human mtDNA is a 16569 nucleotide (nt) double-stranded, circular molecule. This mtDNA is replicated and transcribed inside the mitochondrion via mitochondria-specific DNA and RNA polymerases. Each mtDNA encodes 13 OXPHOS proteins plus the 12S and 16S RNAs and 22 transfer RNAs (tRNAs) necessary for mitochondrial protein synthesis to express these genes. The 12S and 16S ribosomal RNAs (rRNAs) form the scaffold of the bacteria-like mitochondrial ribosomes which initiate translation with a formyl-methionine and are sensitive to bacterial ribosomal inhibitor, chloramphenicol. This latter sensitivity is why prolonged treatment with chloramphenicol is toxic to humans.

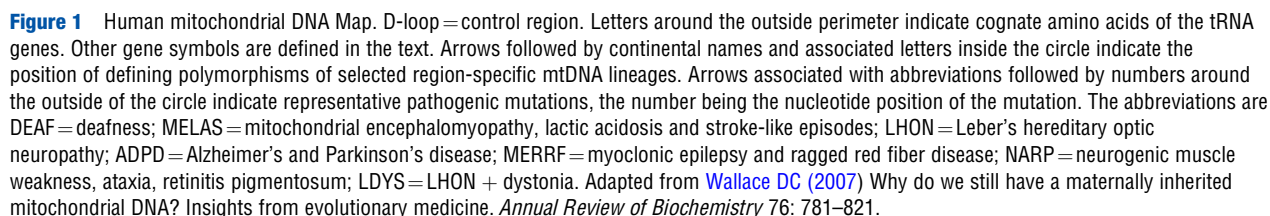

When the mtDNA gene number became sufficiently reduced, the genetic code of the fungal-animal mtDNA lineage began to drift. As a result, today, all members of the fungal-animal lineage use the opal stop codon to encode tryptophan. This change rendered the mtDNA transcripts unintelligible to the nuclear-cytosol, and the further transfer of functional genes from the mtDNA to the nDNA was blocked.

The 13 mtDNA OXPHOS polypeptides include seven (ND1, 2, 3, 4L, 4, 5, and 6) of the 45 polypeptides that constitute OXPHOS complex I; one (cytochrome *b*, *cytb*) of the 11 proteins of complex III; three (COI, II, and III) of the 13 subunits of complex IV; and two (ATP6 and 8) of the about 17 polypeptides of complex V (Figure 1).

OXPHOS (Figure 2) burns hydrogen derived from carbohydrates and fats with oxygen to generate water (H_2O). Carbohydrates are processed by cytosolic glycolysis to pyruvate. The pyruvate then enters the mitochondrion and, in the process, is converted to acetyl-coenzyme A (acetyl-CoA). Acetyl-CoA enters the mitochondrial tricarboxylic acid (TCA) cycle, a central purpose of which is to strip the reducing equivalents (electrons) from the carbon atoms and transfer them either to NAD^+ (nicotinamide adenine dinucleotide, oxidized form) to generate NADH (NAD, reduced form) or to FAD (flavin adenine dinucleotide, oxidized form) to give FADH₂ (FAD, reduced form). Acetyl-CoA and reducing equivalents are also generated within the mitochondrial matrix from fatty acids via the β -oxidation pathway.

The electrons from $NADH + H^+$ are oxidized by a series of OXPHOS complexes called the electron transport chain (ETC) arrayed within the mitochondrial inner membrane. The terminal electron acceptor is oxygen (O_2) and results in water (H_2O). The ETC collects electrons from NADH through complex I (NADH dehydrogenase) or from succinate in the TCA cycle through complex II (succinate dehydrogenase). These and other dehydrogenases transfer the electrons to the shared lipid electron carrier, ubiquinone (coenzyme Q_{10} or CoQ). CoQ can accept two electrons, one to generate ubiquinol (CoQH) and the second to produce ubiquinol (CoQH₂). From CoQH₂ the electrons are transferred to complex III, then cytochrome *c*, then complex IV, and finally to $\frac{1}{2} O_2$ to give H_2O .

The energy that is released as the electrons traverse complexes I, III, and IV, though not through complex II, is used to pump

The energy stored in ΔP can be used to drive many functions. For example, it influences cellular pH (H^+). It is used to transport calcium ions (Ca^{2+}) from the cytosol through carriers in the mitochondrial inner membrane into the mitochondrial matrix, thus regulating cellular Ca^{2+} concentrations. It can also be used to drive the condensation of adenosine diphosphate and phosphate ($ADP + P_i$) to make adenosine triphosphate (ATP). This is achieved by a fifth mitochondrial inner-membrane OXPHOS complex, the ATP synthase, or complex V. Complex V couples the flow of protons back into the mitochondrial matrix through an enzyme proton channel with the condensation of $ADP + P_i$ to give ATP. Mitochondrial ATP is then exchanged across the mitochondrial inner membrane for

The efficiency by which ΔP is converted to ATP is known as the coupling efficiency. Tightly coupled OXPHOS generates the maximum ATP and minimum heat, while loosely coupled OXPHOS requires more calories to produce the same amount of ATP, the excess calories generating additional heat. Whether calories go through an intermediate of ATP or are converted directly to heat, ultimately, each calorie burned produces the same amount of heat. In endotherms like humans this heat generation is regulated to maintain a stable body temperature.

As a by-product of OXPHOS, the mitochondria generate most of the reactive oxygen species (ROS or oxygen radicals) produced within eukaryotic cells. This results from the misdirection of electrons from the early stages of the ETC surrounding ubiquinone directly to O_2 to generate superoxide anion ($O_2^{\cdot -}$). OXPHOS complex I generates $O_2^{\cdot -}$ in the matrix and this $O_2^{\cdot -}$ is converted to hydrogen peroxide (H_2O_2) by the matrix Mn superoxide dismutase. Complex III produces $O_2^{\cdot -}$ in the inter-membrane space and this $O_2^{\cdot -}$ is detoxified by Cu/ZnSOD located within the inter-membrane space and the cytosol. In the presence of reduced transition metals H_2O_2 can be

Figure 2 Five features of mitochondrial metabolism relevant to the pathophysiology of disease: (1) energy production by oxidative phosphorylation (OXPHOS), (2) reactive oxygen species (ROS) generated by OXPHOS as a signaling system and when excessive as a toxic by-product, (3) regulation of mitochondrial and cellular oxidation–reduction status, (4) regulation of cellular and mitochondrial Ca^{2+} concentrations, and (5) regulation of apoptosis through activation of the mitochondrial permeability transition pore (mtPTP). I, II, III, IV, and V = OXPHOS complexes I–V; ADP or ATP = adenosine di- or triphosphate; ANT = adenine nucleotide translocator, CytC = cytochrome *c*; GPx = glutathione peroxidase-1; LDH = lactate dehydrogenase; MnSOD = manganese superoxide dismutase or SOD2; NADH = reduce nicotinamide adenine dinucleotide; TCA = tricarboxylic acid cycle; VDAC = voltage-dependent anion channel. Adapted from Wallace DC (2007) Why do we still have a maternally inherited mitochondrial DNA? Insights from evolutionary medicine. *Annual Review of Biochemistry* 76: 781–821.

reduced by single electron transfer to hydroxyl radical ($\cdot\text{OH}$) which is the most toxic ROS. Consequently, the cell attempts to minimize H_2O_2 by its conversion to water (H_2O) via a two-electron transfer mediated by glutathione peroxidase (GPx1) or conversion to water and oxygen by catalase (Figure 2).

Glutathione peroxidase reduces H_2O_2 to H_2O by using electrons donated from reduced glutathione (2GSH) to generate in oxidized glutathione (GSSG). GSSG is reduced again via glutathione reductase using electrons derived from $\text{NADPH} + \text{H}^+$. $\text{NADPH} + \text{H}^+$ is used since $\text{NADH} + \text{H}^+$ has insufficient reducing power to reduce GSSG. Therefore, to transfer the electrons from $\text{NADH} + \text{H}^+$ to NADP^+ additional energy is required. This energy is collected from the electrochemical gradient (ΔP) by the mitochondrial inner membrane protein, the nicotinamide nucleotide transhydrogenase. Hence, under normal health circumstances, mitochondrial ROS is carefully regulated based on electron flux (redox) and thus energy flux.

Mitochondrially generated ROS has a critical signaling function permitting the nucleus to monitor the energetics of the mitochondrion. However, if OXPHOS is inhibited by a block in one of the OXPHOS complexes or there is an excess of calories relative to demand for ΔP causing ΔP to become maximized, then the ETC stalls, all of the electron carriers become reduced, and the excess electrons are transferred as single electrons to O_2 accelerating ROS production. Excessive ROS can overwhelm the

antioxidant defense systems and persist long enough to damage mitochondrial proteins, lipids, and nucleic acids. This increased oxidative stress can ultimately compromise mitochondrial energy production and destroy the mtDNA's capacity to maintain OXPHOS function resulting in energetic failure.

Cells with faulty mitochondria are removed by programmed cell death (apoptosis) through the activation of the mitochondrial permeability transition pore (mtPTP). The mtPTP spans the mitochondrial inner and outer membrane. While the structure of the mtPTP remains unclear, proteins that have been implicated in its function include the outer-membrane VDAC, the inner-membrane ANT, the pro- and anti-apoptotic Bcl2-Bax gene family proteins, cyclophilin D, and the mitochondrial transporter protein (TSPO also known as the peripheral benzodiazepine receptor). This complex senses changes in mitochondrial ΔP , adenine nucleotides, ROS, and Ca^{2+} , and when these factors get sufficiently out of balance, the mtPTP is activated and opens a channel between the cytosol and the mitochondrial matrix. This depolarizes ΔP , frequently causing the mitochondrion to swell, and produces a large channel in the outer membrane. The perforation of the mitochondria outer membrane permits proteins stored in the mitochondrial inter-membrane space to escape into the cytosol. These proteins include cytochrome *c* which activates cytosolic Apaf-1 to convert pro-caspases 9 to an active protease.

Caspase 9 then cleaves and activates caspases 1 and 3. Caspases 1 and 3 and others then degrade all of the proteins of the cell. Apoptosis initiating factor (AIF) and caspase activated DNase (CAD) are also released and transported to the nucleus where they degrade the nDNA (Figure 2).

MtPTP-induced apoptosis means that cells with faulty mitochondria are removed from the tissue so that the energetic failure of the cell does not compromise the function of the remaining cells of the tissue and organ. However, post-mitotic tissues have a finite number of cells. As more cells are lost due to mitochondrial-induced apoptosis, the tissue cellularity declines. Ultimately, insufficient cells remain in the tissue to maintain normal tissue function and symptoms result. Generally, we are born with sufficient extra cells that we continue to function past reproductive age. However, there is no evolutionary advantage for maintaining the body beyond reproduction so eventually the tissues run low on cells and the individual dies. Thus, the pathophysiology of degenerative diseases and aging is the result of age-related mitochondrial failure, but the symptoms of old age are the product of the secondary loss of tissue cellularity.

Mitochondrially induced apoptosis also serves a second function. Many of the mitochondrial proteins are highly homologous to those of other bacteria. If the mitochondria were released into the circulation, they could induce an immunological response. Hence, apoptotic degradation of the cell and its mitochondria avoid the release of the mitochondrial antigens into the circulation.

Mitochondrial Genetics and Epigenomics

The nonchromosomal nature of the mtDNA means that it is not inherited according to the Mendel laws. The human mtDNA is inherited exclusively from the mother, the father's mtDNA being destroyed at fertilization. Since the mtDNA is bathed in ROS, it is prone to mutation. Therefore, individual mtDNAs within a cell can become mutated creating a mixture of mutant and normal mtDNAs, a state known as heteroplasmy. When a heteroplasmic cell undergoes cytokinesis, the mutant and normal mtDNAs are stochastically distributed between the daughter cells, a process that occurs during both mitosis and meiosis. This replicative segregation can generate a continuous array of genotypes from pure normal to pure mutant. The higher the proportion of the mutant mtDNAs, the lower the number of functional enzyme complexes available to sustain OXPHOS. Ultimately, the energy output of the mitochondria falls below the minimal energy requirements for the cell, resulting in cellular dysfunction, the bioenergetic threshold.

The high mtDNA mutation rate and critical function of the mtDNA genes should result in a high frequency of deleterious mtDNA mutations. If this were the case, the genetic load resulting from mtDNA mutations would compromise the robustness of the species, ultimately leading to extinction. Such a genetic catastrophe is prevented in mammals by an inter-ovarian selection system that eliminates those proto-oocytes with severe mitochondrial defects prior to fertilization. This pre-fertilization selection system mitigates the genetic load of the high mutation rate while at the same time permitting a wide range of potentially adaptive mutations to be

regularly introduced into the species to produce genetic diversity. Since the mtDNA controls the energetics of the cell, this system provides the genetic diversity needed for a species to genetically adapt to regional differences in the energetic environment within a species' niche.

While nDNA mutations in mitochondrial genes could also permit adaptation to environmental change, mutations in the nDNA can only be selected for or against following fertilization and the development of the individual. Since most structural gene mutations are deleterious, the nDNA mutation rate must be kept low. Hence, regional adaptive polymorphisms in the nDNA are relatively rare, consequently the mtDNA mutations are the primary genetic variation for intra-species adaptation to regional and long-term environmental changes.

The over one thousand nDNA-encoded mitochondrial genes dispersed across the chromosomes also play an essential role in human adaptation, but not through mutation. Many environmental changes are both short term and reversible. This includes changes in the energetic environment that occur daily, monthly, annually, and over recent generations. Since genetic mutations are irreversible, longer-term reversible adaptive changes in energetics are achieved by changes in the expression of the nDNA-encoded mitochondrial genes via the epigenome through modification of chromatin structure. Shorter-term reversible changes are achieved through energetic modification of the proteins of the cellular signal transduction pathways.

Both the chromatin and the signal transduction pathways are modulated by protein and DNA modifications using mitochondrially derived high-energy intermediates, including ATP, acetyl-CoA, and S-adenosylmethionine (SAM). The histones that package the nDNA into nucleosomes have positively charged amino terminal tails. When unmodified, the positive charges of the histone tails bind to the negative charges of the DNA sugar-phosphate backbone shutting down transcription and replication. However, when calories are in excess, then intra-cellular ATP, acetyl-CoA, and SAM levels are high. These compounds phosphorylate, acetylate, or methylate the histone tails neutralizing the positive charge. This releases the grip of the histones on the DNA and opens up the chromatin for transcription and replication. Hence, when energy is flowing through the mitochondria, the mitochondrial high-energy products are prevalent and the mitochondrial high-energy intermediates activate nDNA gene expression for growth and reproduction. When energy flow subsides, mitochondria high-energy intermediates decline, histone modification declines, and nDNA transcription shuts down. The same logic can be generalized to the regulation of the cellular signal transduction pathways that are mediated by phosphorylation and acetylation.

Therefore, bioenergetics permits three levels of adaptation: adaptation to reversible environmental changes occurring over days to generation through energetic modulation of epigenomic regulation of nDNA mitochondrial gene expression, adaptation to stable regional variation within the species' niche over thousands of years through high-frequency mtDNA mutations, and adaptation to different energy reservoirs (eating nuts vs. insects for Darwin's finches) through nDNA gene mutations over millions of years that change the species' anatomy (the beaks of finches) resulting in speciation. This evolutionary perspective now permits interpretation of the array of disease-causing mitochondrial dysfunctions.

Disease-Causing mtDNA Mutations

A wide range of pathogenic mtDNA mutations have been described over the past 20 years. The first inherited pathogenic mtDNA mutations were base substitution mutations. These included the mtDNA missense mutation in the ND4 gene at nt 11778 that converted the arginine at codon 340 to histidine and causes Leber's hereditary optic neuropathy, a form of sudden-onset, mid-life, blindness, and the tRNA^{Lys} nt 8344 base substitution protein synthesis mutation that causes myoclonic epilepsy and ragged red fiber disease. The first spontaneous mtDNA disease-causing mutations were deletions associated with mitochondrial myopathy. Deletions in the mtDNA are now known to cause chronic progressive external ophthalmoplegia, the Kearns–Sayre syndrome, or the Pearson's marrow pancreas syndrome. Since these discoveries, a plethora of pathogenic mutations have been described in the mtDNA.

Mitochondrial defects primarily affect the more energetic tissues including central nervous system, heart, muscle, kidney, and endocrine systems. While the frequency of deleterious mtDNA mutations in the human population is high, in fact only the milder of all possible deleterious mutations generally appear in the population due to the filtering function of the intra-ovarian selection system. A catalogued identified mtDNA pathogenic base substitution mutations is available at the MITOWEB website.

The high mtDNA mutation rate, paired with intra-ovarian selection, permits the continuous introduction of new mtDNA nucleotide substitutions into the population. These range from deleterious to advantageous, depending on the environmental and genetic context in which the mtDNA mutations arise. Mutations that are beneficial in a particular environment will preferentially reproduce and become enriched in the region. Since the mtDNA is exclusively maternally inherited, and can only change by sequential mutations along radiating maternal lineages, this results in the development of regional groups of related mtDNA haplotypes derived from the mtDNA in which the original adaptive mutation first appeared. Such regional groups of related haplotypes are called haplogroups.

By defining the regional mtDNA haplogroups and deducing the sequence of mutation events that connect the haplogroups, it has been possible to reconstruct the history of woman (Figure 3). These studies have revealed that humans arose in Africa about 150 000–200 000 years before present (YBP). Sub-Saharan African mtDNAs radiate into four African-specific lineages: L0, L1, L2, and L3, the most ancient mtDNA lineages being found among the Khoisan Bushman. About 65 000 YBP, L3 gave rise to two new lineages in northeastern Africa, designated M and N. Only M and N left Africa to colonize all of Eurasia, with one group migrating along the southeastern Asian coast to colonize Australia. In Europe, lineage N gave rise to the European-specific lineages H, I, J, K, T, U, V, W, and X. In Asia, both M and N radiated to generate a

Figure 3 Global radiation of mtDNA types showing the regional association of mtDNA types. Capital letters represent major region groups of related haplotypes (haplogroups). In sub-Saharan Africa, haplogroup L0, which arose between 150 000 and 200 000 years before present (YBP), radiated into haplogroups L1, L2, and L3. At about 65 000 YBP haplogroup L3 gave rise to haplogroups M and N in northeastern Africa. M and N then left Africa in two directions. A southeastern migration moved through Southeast Asia, ultimately giving rise to Australian mtDNAs. A northeastern migration colonized Eurasia, with haplogroup N giving rise to the European mtDNA haplogroups H, I, J, K, T, U, V, W, and X and to the Asian haplogroups A, B, F, etc. Haplogroup M radiated into Asia to give rise to Asian haplogroups C, D, G, etc. Haplogroups A, C, and D became enriched in northeastern Siberia and crossed the Bering land bridge about 20 000 YBP. European-like haplogroup X arrived in Central North America about 15 000 YBP and haplogroup B migrated along the Asian and Bering coasts into southern North America, Central America, and northern South America about 12 000–15 000 YBP. X and B mixed with the haplogroups A, C, D mtDNA to generate the Amerind paleo-Indian population. About 7000–9000 YBP derivatives of haplogroup A crossed the Bering Strait to generate the Na-Dene, and around 3000–5000 YBP derivatives of predominantly haplogroup D but also A and C crossed the Bering Strait to give rise to the Eskimos and Aleuts. The +/–, +/+, –/– represent important M and N diagnostic restriction sites. The ages were calculated using the empirically determined mtDNA sequence evolution rate of 2.2–2.9%/million years (MYR). Adapted from Wallace DC (2007) Why do we still have a maternally inherited mitochondrial DNA? Insights from evolutionary medicine. *Annual Review of Biochemistry* 76: 781–821.

plethora of Asian-specific mtDNA lineages, including A, B, and F from N and C, D, and G from M. Among all of the Asian mtDNA lineages, only A, C, and D successfully occupied arctic Chukotka in northeastern Siberia. When the Bering land bridge appeared, individuals bearing these mtDNAs moved to the Americas about 20 000 YBP. A subsequent coastal migration brought lineage B to mix with A, C, and D about 12 000–15 000 YBP, and another migration across the arctic brought the European haplogroup X to the Great Lakes region of North America about 15 000 YBP. The sum of these migrations generated the Paleo-Indians. A migration from around the Sea of Okhotsk about 7000–9000 YBP brought a modified A to find the Na-Dene. Finally, recent migrations bringing predominantly D but also A and C gave rise to the Eskimos and Aleuts.

Since these regional haplogroups permitted individuals to adapt to local bioenergetic environments, a change in the local environment may result in a mismatch between the mtDNA genotype and the environment, predisposing the individuals to disease. The migration of indigenous people out of their traditional homelands and cultural globalization of the Northwestern high-fat European diet have contributed to an increasing mismatch between mitochondrial genotype and bioenergetic environment. This results in a marked rise in predisposition to a wide range of metabolic and degenerative diseases, including diabetes and obesity, Alzheimer's and Parkinson's disease, cardiovascular disease, predisposition to blindness, sensitivity to infections, tolerance of trauma, etc.

Further exacerbation of the negative effects of the mismatch between mtDNA genes and environment is the rise in toxic industrial and agriculture chemical toxins in the environment, many of which are potent inhibitors of mitochondrial function. These factors interact to contribute to the rapid rise in complex diseases in the industrialized countries.

Disease Causing nDNA-Mitochondrial Gene Mutations

Pathogenic mutations in nDNA-encoded mitochondrial genes fall into two broad categories: mutations that affect the mitochondrial metabolic functions and mutations that affect the biogenesis of the mitochondrion. Deleterious mutations in the structural genes can result in a wide range of clinical symptoms. However, the most well-recognized clinical syndrome associated with function defects in OXPHOS is Leigh syndrome. Leigh syndrome typically affects children that had previously seemed relatively normal. At some point the children experience a rise in temperature and then progressively lose intellectual and motor milestones in association with lesions in the basal ganglia of the brain. In many cases, the children ultimately die. Leigh syndrome has been associated with mutations that inactivate polypeptides for the structure and assembly of key energy-generating enzymes, including pyruvate dehydrogenase and complexes I, II, III, IV, and V. Severe mtDNA mutations can also result in Leigh syndrome.

In addition to structural gene defects, nDNA mutations have been observed that affect mitochondrial biogenesis and turnover. Pathogenic mutations can occur in the mtDNA replication genes mtDNA polymerase γ (POLG) and Twinkle helicase resulting in multiple mtDNA deletions and causing mitochondrial myopathy and neurodegenerative disease,

among other representations. Mutations in the mitochondrial nucleotide metabolism genes for thymidine kinase 2 and deoxyguanosine kinase result in mtDNA depletion and cause various syndromes depending on the organ experiencing the mtDNA depletion, while mutations in the thymidine phosphorylase result in both mtDNA deletions and depletion and cause myoneurogastrointestinal encephalopathy. Mutations in mitochondrial fission and fusion genes such as Opa1 cause optic atrophy and in Mfn2 cause Charcot-Marie-Tooth 2A2 peripheral neuropathy. Finally, mutations in the mitochondrial autophagy (mitophagy) turn over genes PINK1 and parkin cause familial forms of Parkinson's disease.

Diseases Caused by Defects in the Epigenome

While it is commonly asserted that epigenomic changes link the environment to the etiology of complex disease, the environmental factors that modulate the epigenome and the pathophysiological consequences of alterations in the epigenome remain ill defined. The realization that virtually all epigenomic and signal transduction pathway modifications are mediated by reactions using high-energy intermediates implicates energy flux as central to epigenomic regulation and hence to the interaction between the environment and the genome. This role of energy flow in modulating the epigenome and the signal transduction pathways is mediated in two ways. In the first, the mitochondrially generated ATP, acetyl-CoA, and SAM modify and regulate the proteins of chromatin, signal transduction pathways, and metabolism. In the second, the mitochondria regulate cellular oxidation–reduction (redox) status of the cell through the $\text{NAD(P)}^+/\text{NAD(P)H}+\text{H}^+$ ratios, ROS production, and alteration of protein thiol/disulfide equilibrium.

The HIF-1 transcription factor family, which mediates the cellular response to hypoxia, provides an example of the importance of ROS and redox in regulating cellular functions. When activated, HIF-1 upregulates glycolysis and stimulates tissue vascularization. Concurrently, it downregulates mitochondrial function in four ways: it modifies the oxygen interaction of complex IV by switching from the COX4-1 isoform to the COX4-2 isoform, inactivates pyruvate dehydrogenase by phosphorylation, inhibits mitochondrial biogenesis by suppression of c-myc, and stimulates mitochondrial degradation by mitophagy. HIF-1 activity is increased by the stabilization of HIF-1 α , which normally turned over as rapidly as it is synthesized. However, in hypoxia and with increased mitochondrial ROS and succinate production, the enzyme that turns over HIF-1 α , prolylhydroxylase domain protein 2, is inactivated and HIF-1 α is stabilized.

HIF-1 α interacts with HIF-1 β resulting in the active transcription factor. However, once generated, HIF-1 is further modulated through the oxidation–reduction of its thiol/disulfide-coupled amino acids by the mitochondrial and cytosolic redox status which is directly linked to energy flow through the mitochondrion.

Evidence that the epigenome is regulating cell energy metabolism has been found both for cancer and in imprinting diseases. In hepatomas, changes in methylation activate the hexokinase II gene. Hexokinase II then binds to mitochondrial VDAC and coops mitochondrial ATP to drive glycolysis.

In Wilm's tumor and Beckwith–Weideman syndrome (chromosome 11q15.5), epigenomic changes activate the insulin-like growth factor 2 pathway which regulates OXPHOS and glycolysis. In the imprinting disease, Angelman syndrome, due to modifications in the chromosome15q11–13 region, the brain hippocampal cells in the mouse model have been found to have shrunken mitochondria and reduced complex II–III activity. Mutations in the *LMNA*, gene whose protein is concentrated on the inside of the nuclear envelope and is also present in the nucleoplasm, can produce all of the same clinical phenotypes as seen in mitochondrial disease (myopathy and cardiomyopathy, peripheral neuropathy, diabetes and metabolic syndrome, and premature aging). Cells of patients harboring *LMNA* mutations associated with diabetes and metabolic syndrome have been reported to have mitochondrial defects.

Conclusions

For the past 450 years, Western medicine has focused on the anatomical features of disease, and for the past 125 years on genetic traits that behaved according to the Mendel laws. These two features were internally consistent in that all of the anatomical genes are also Mendelian. Belief that these two perspectives encompassed all relevant phenomena has led to two erroneous corollaries: that tissue-specific symptoms are due to tissue-specific defects and that familial traits that do not Mendelize must be environmental. However, life requires anatomy, energy, and information, and the role of energy failure and the non-Mendelian energy genetics in human disease has been essentially overlooked. It is now clear that systemic defects in energy metabolism can cause tissue-specific symptoms, energy diseases can be inherited in a non-Mendelian fashion, and the nongenetic regulation of the nDNA-encoded energy genes based on environmental energy availability and use have a major effect on human characteristics and predisposition to metabolic and degenerative diseases, cancer and aging. These realizations indicate that most of the common metabolic and degenerative diseases are not anatomical but energetic and that these diseases have appeared genetically complex because their inheritance has been interpreted using the Mendelian laws which are only partially applicable.

Glossary

Electrochemical gradient The driving force inherent in an ion gradient across a membrane, made up of two components: the membrane potential and the ion concentration gradient.

Gibbs free energy A thermodynamic term that expresses the extent to which a process is displaced from equilibrium and hence defines its capacity to do work.

Proton circuit The closed cycle comprising protons pumped across, for example, the mitochondrial inner

membrane and reentering via the adenosine triphosphate synthase or a leak pathway.

Proton conductance The conductance of a membrane to protons calculated by applying Ohm's law to the proton circuit.

Redox couple A reduced/oxidized pair, such as nicotinamide adenine dinucleotide hydrogenase/nicotinamide adenine dinucleotide.

Redox potential A thermodynamic measure of the tendency of a redox couple to gain or lose electrons.

Bioenergetics is the study of the molecular mechanisms by which energy, made available by catabolic metabolic pathways or by light capture in photosynthesis, is transformed and made available for cellular processes of growth, motility, and survival. Traditionally, the field has largely focused on studies of bacteria, mitochondria, and chloroplasts, although the principles, largely involving the generation and utilization of ion gradients across membranes, are much more generally applicable.

Thermodynamics

Two factors are required for a biochemical reaction to occur spontaneously: the process should involve an increase in the entropy of the system and its surroundings and there should be a mechanism, usually enzymatic, to lower the energy barrier sufficiently to allow the transformation to occur at a significant rate. The entropy difference is the realm of thermodynamics, whereas the energy barrier helps to define the rate of the process.

The simplest thermodynamics deals with the limiting case of isolated systems that exchange neither material nor energy across their boundaries and, therefore, have no influence on their surroundings. Closed systems exchange energy but not material with their surroundings, whereas real biological systems are open, that is, exchanging both energy and material (substrates and products). The treatment of open systems is complex and requires nonequilibrium thermodynamics; however, the equilibrium thermodynamics of closed systems can be used to obtain important information, such as the conditions under which a given reaction would be at equilibrium and the extent to which the actual reaction in the cell is displaced from equilibrium. Although equilibrium thermodynamics gives no information as to the rate of a reaction, it can unequivocally exclude any process that is energetically impossible.

Gibbs Free Energy

The entropic driving force is equally valid for closed and isolated systems; however, analysis is complicated by the

effects of the energy transfer across the boundaries of the system affecting the entropy of the surroundings. The Gibbs free energy change, ΔG , is a function that, under conditions of constant temperature and pressure, corrects for the entropy change in the surroundings and enables equilibrium to be calculated only using parameters for the system itself. Gibbs energy changes are used not only to study a reaction in solution, but also to quantify reduction–oxidation (redox) reactions occurring, for example, in the mitochondrial respiratory chain, to calculate the available energy in an ion gradient, and to compare the energy available from absorption of light quanta in photosynthesis.

A basic understanding of bioenergetics is considerably helped by the use of simple analogies. Figure 1 shows schematically the content of Gibbs energy (G) in a closed system when the reaction $A = B$ is displaced on either side of equilibrium. The slope of the parabola at any point represents the Gibbs energy change (ΔG). The bottom of the parabola represents the equilibrium condition: the content of Gibbs free energy is at a minimum and the tangent to the slope, ΔG , is zero. Equilibrium is the lowest energy state and a small conversion of substrate to product at equilibrium causes no free energy change. The left side of the parabola represents reaction conditions that have not yet proceeded as far as equilibrium. The slope ΔG is negative, which indicates that the reaction can proceed spontaneously (as long as a pathway exists). The further from equilibrium, the greater is the slope; that is, the Gibbs energy change becomes more negative and more energy is available from a conversion of substrate to product at those concentrations. Beyond the equilibrium point, the slope is uphill. Reactions cannot proceed beyond equilibrium without some independent energy input.

The Gibbs free energy change can be quantified as a function of the displacement from equilibrium

$$\Delta G(\text{kJ mol}^{-1}) = -2.3RT \log_{10} \left(\frac{K}{\Gamma} \right) \quad [1]$$

where R is the gas constant, T is the absolute temperature, K is the equilibrium constant under the conditions of the

Figure 1 Schematic representation of Gibbs energy in relation to displacement from equilibrium. (a) Gibbs energy (G) is at a minimum at equilibrium and Gibbs energy change (ΔG), given by the slope of the parabola, is zero. (b) Before equilibrium, the slope (ΔG) is negative and the reaction can proceed spontaneously. (c) Beyond equilibrium, the slope is uphill and an additional energy input would be required. (d) The further the reaction is displaced from equilibrium, the greater is the slope; that is, ΔG becomes more negative. Adapted from Nicholls DG and Ferguson SJ (2002) *Bioenergetics* 3. London: Academic Press.

determination, and Γ is the mass-action ratio of the concentrations of substrates and products measured in the cell or assay mixture. Put more simply, ΔG changes by approximately 5.7 kJ mol^{-1} for each 10-fold displacement from equilibrium. Note that this equation corresponds to the more familiar form that involves standard free energy, for example,

$$\Delta G = \Delta G^0 + 2.3RT \log_{10} \left(\frac{[C]^c [D]^d}{[A]^a [B]^b} \right) \quad [2]$$

but is more logical and symmetrical, emphasizing displacement from equilibrium, rather than the frequently misused abstract concept of standard free energy.

Adenosine Triphosphate

Adenosine triphosphate (ATP) synthesis from adenosine diphosphate (ADP) and phosphate (P_i) and the reverse hydrolysis reaction are the dominant reactions in the distribution and utilization, respectively, of Gibbs free energy in the cell. The ATP synthesis reaction is held up to 10^{10} -fold beyond its equilibrium and thus requires an input of Gibbs free energy of approximately $10 \times 5.7 = 57 \text{ kJ mol}^{-1}$. Conversely, the hydrolysis of 1 mol of ATP can yield up to 57 kJ mol^{-1} . There is no magic property associated with ATP (such as the myth of the high-energy bond) that fits it for this universal role, except that the equilibrium constant of the reaction is such that a sufficient concentration of ADP remains in a functioning cell to bind to the ATP synthase (see below).

The ATP synthesis reaction is usually expressed in shorthand form, ignoring water, ionization, pH, and chelating ions such as Mg^{2+} ; that is,

This may only be used as the basis for thermodynamic calculations if the equilibrium constant is known under exactly identical conditions, in which case the common factors cancel out of the ratio Γ/K in eqn [1].

Redox Potentials

Redox reactions are those that involve coordinate oxidation of one substrate and the reduction of another. An example of a redox reaction occurring in the cytoplasm is that catalyzed by lactate dehydrogenase:

Redox reactions can be considered hypothetically as the sum of two linked half-reactions:

and

All biological redox reactions can be considered to involve primary electron transfer, although in many cases the increased negative charge on the reduced component leads to the subsequent binding of one or more protons; thus, ubiquinone reduction to ubiquinol in the respiratory chain involves the addition of two electrons followed by two protons, whereas NAD^+ reduction to NADH requires the addition of two electrons followed by one proton (eqn [5]).

A reduced/oxidized pair, such as nicotinamide adenine dinucleotide hydrogenase/nicotinamide adenine dinucleotide (NADH/NAD^+), is a redox couple and the equilibrium of the half-reaction can be defined in terms of its half-reduction redox potential (the potential at which the concentrations of oxidized and reduced species are equal). A redox couple with a more negative redox potential will tend to oxidize one with a more positive potential. Zero is defined as the potential of a $\frac{1}{2}\text{H}_2/\text{H}^+$ couple at pH 0 when H_2 is 1 atm. Important half-reduction potentials include those for $\text{NADPH}/\text{NADP}^+$ and NADH/NAD^+ (both -320 mV), fumarate/succinate ($+30 \text{ mV}$), ubiquinol/ubiquinone ($+60 \text{ mV}$), and reduced/oxidized cytochrome c ($+220 \text{ mV}$). The important $\text{H}_2\text{O}/\frac{1}{2}\text{O}_2$ couple has a redox potential of $+820 \text{ mV}$ when O_2 is present at 1 atm and water is 55 M.

Redox potentials are not constants, but vary with the state of reduction of the couple. The redox potential of a one-electron reduction couple becomes 60 mV more negative for each 10-fold increase in the reduced/oxidized ratio. Thus, although the standard hydrogen electrode at pH 0 has a redox potential of zero, at pH 7 when the proton concentration is only 10^{-7} M , the redox potential is -420 mV . Two electron reductions change by 30 mV per decade; thus, the NADH/NAD^+ couple in mitochondria is typically 10% reduced and, therefore, has a redox potential of approximately $-320 + 30 = -290 \text{ mV}$, whereas the $\text{NADPH}/\text{NADP}^+$ pool is at least 90% reduced and so operates at approximately -350 mV .

Although the historical origin of redox potentials (in electrochemistry) may obscure the relationship, redox changes are governed by Gibbs free energy principles; indeed, the ΔG

associated with the difference in redox potential between two couples can be simply calculated as

$$\Delta G = -nF\Delta E_h \quad [6]$$

where n is the number of electrons transferred and F is the Faraday constant ($0.965 \text{ kJ mol}^{-1} \text{ mV}^{-1}$). As a rough rule of thumb, a mole of electrons falling through a potential of 1 V makes 100 kJ of Gibbs free energy available, and 2 mol of electrons passing from NADH to O_2 through the respiratory chain corresponds to a ΔG of -224 kJ . Note that this is compatible with the formation of approximately 3 mol of ATP.

Ion Electrochemical Potential Differences

The concept of Gibbs free energy as displacement from equilibrium can be extended to gradients of ions and solutes across biological membranes. Two components must be considered: that due to a difference in concentration between the two aqueous compartments and (if the species is charged) that due to the difference in electrical potential between the compartments (usually termed the membrane potential, not to be confused with any surface charge on the membrane itself). The Gibbs free energy is simply the sum of the two components (hence electrochemical):

$$\Delta G(\text{kJ mol}^{-1}) = -mF\Delta\psi + 2.3RT\log_{10} \frac{[X^{m+}]_B}{[X^{m+}]_A} \quad [7]$$

where m is the charge on the ion, $\Delta\psi$ is the membrane potential in millivolts, and X^{m+} is the concentration of the ion in compartment A or B.

The ion of most interest in bioenergetics is the proton. The equation for the proton electrochemical gradient ($\Delta\mu_{\text{H}^+}$) is rather simple, due to the logarithmic nature of pH:

$$\Delta\mu_{\text{H}^+}(\text{kJ mol}^{-1}) = -F\Delta\psi + 2.3RT\Delta\text{pH} \quad [8]$$

The mitochondrial convention is that ΔpH is the pH outside minus that in the matrix and is usually negative.

The proton electrochemical gradient is usually expressed in units of voltage. This proton-motive force, Δp , is defined as

$$\Delta p (\text{mV}) = -(\Delta\mu_{\text{H}^+})/F = \Delta\psi - 60\Delta\text{pH} \quad [9]$$

Photons

The Gibbs free energy available from a single photon is equal to Planck's constant times frequency, that is, $h\nu$, where ν is the frequency of the radiation. A mole (Avogadro's number) of photons corresponds to a ΔG of $120\,000 \lambda \text{ kJ mol}^{-1}$, where λ is the wavelength in nanometers. For 600-nm red light, this corresponds to 200 kJ mol^{-1} . Note that the absorption of such a photon would theoretically be capable of lowering (making more negative) the potential of an electron by 2 V.

The Thermodynamics of Bioenergetic Interconversions

The bioenergetic processes occurring in mitochondria involve the sequential conversion of redox energy into proton-motive force and of proton-motive force into the Gibbs free energy of the ATP pool. As each is based on Gibbs free energy, the interconversion is very simple. Consider a respiratory chain complex that transfers

two electrons through a redox span of $\Delta E_h \text{ mV}$. If the complex pumps n protons against a proton-motive force of $\Delta p \text{ mV}$, equilibrium would be reached when $n\Delta p = 2\Delta E_h$. For the complex to work in the forward direction, therefore, $n\Delta p > 2\Delta E_h$. Roughly speaking, the forward rate of the complex is proportional to the disequilibrium for small displacements, which is why respiration accelerates when the proton gradient is lowered.

The equilibrium condition for the ATP synthase, where Δp is expressed in kilojoules per mole and Δp is expressed in millivolts, requires the Faraday constant, $\Delta G_{\text{ATP}} = mF\Delta p$, where m represents the number of protons required to generate 1 mol of ATP. As the ATP synthase is reversible, it can operate in the forward direction (ATP synthesis) when $\Delta G_{\text{ATP}} < mF\Delta p$ and in the reverse direction (ATP hydrolysis) when $\Delta G_{\text{ATP}} > mF\Delta p$.

Mitochondrial Respiration Rate: The Proton Circuit

A simple but immensely powerful aid to understanding the relationships between proton-motive force, respiration, and proton reentry pathways is to use a simple electrical analogy

Figure 2 The analogy between the proton circuit and a simple electrical circuit. (a) Open circuit. Zero current (no respiration), potential (Δp) maximal. (b) Circuit completed, current flows (respiration). Useful work done (ATP synthesized). Potential (Δp) less than maximal. (c) Short-circuit introduced; energy dissipated, potential low, respiration maximal. Adapted from Nicholls DG and Ferguson SJ (2002) *Bioenergetics 3*. London: Academic Press.

(Figure 2). Because there is a fixed stoichiometry between electron flow (and hence respiration) and proton translocation, and also because protons must reenter the mitochondrial matrix at exactly the same rate that they are pumped out, the proton current, J_{H^+} , circulating around the proton circuit, will equal the rate of respiration times the H^+/O (protons pumped divided by oxygen utilized) stoichiometry of the respiratory chain.

Because the current and potential (Δp) in the proton circuit are known, Ohm's law can be used to calculate the resistance (or its reciprocal, i.e., the conductance, $C_{\text{M}}\text{H}^+$) of the inner membrane to proton reentry:

$$C_{\text{M}}\text{H}^+ = J_{\text{H}^+} / \Delta p \quad [10]$$

Two major components of proton conductance are that which occurs through the ATP synthase, which is tightly coupled to the rate of ATP synthesis, and an endogenous proton leak possessed by all mitochondria. One specialized tissue, brown adipose tissue, possesses an additional controllable

proton leak catalyzed by an uncoupling protein that allows respiration, and heat production, to occur without concomitant ATP synthesis.

Glossary

Biocytin Biotinylated lysine which is formed between the carboxyl group of biotin and the epsilon amino group on the side chain of lysine.

Biotin A small, water-soluble vitamin belonging to the B-complex group; it is also known as vitamin H.

Biotinidase A mammalian enzyme that can hydrolyze biotin from either biocytin or short

biotin-containing peptides, thus facilitating recycling of the vitamin.

Biotin protein ligase The enzyme [E.C. 6.3.4.15] responsible for covalent attachment of a biotin moiety onto a biotin-enzyme; it is also known as the biotin-inducible repressor (BirA) in some prokaryotes and holocarboxylase synthetase in mammalian cells.

Historical Perspective

At the end of the nineteenth century, it was observed that extracts from liver and meat could serve as effective treatments for skin lesions induced by a diet of raw egg. Earlier studies had identified a heat-stable factor in the same extracts that was also required for yeast growth. In 1935, Kogl and Tannis isolated this factor from egg yolk and called it biotin. The essential growth factor present in the meat extracts, which had become known as vitamin H (*Haut*, 'skin' in German), was found to be identical to biotin. Later, it was discovered that avidin, a biotin-binding glycoprotein, was the toxic component of raw eggs. The structure of biotin was determined in 1942 and confirmed by chemical synthesis and X-ray analysis.

During the 1950s, it became evident that biotin is involved as a cofactor for a class of enzymes that catalyze a variety of carboxyl transfer reactions. It was first demonstrated that β -methylcrotonyl-coenzyme A (CoA) carboxylase, a biotin-requiring enzyme that catalyzes a step in the degradation of leucine, was capable of carboxylating free biotin. It soon became apparent that, in the cell, biotin functions as a cofactor only when bound to protein and that biotin is covalently attached to the ϵ -amino group of a specific lysine residue of propionyl CoA carboxylase. Subsequently, it was demonstrated for other biotin enzymes that the biotin prosthetic group is attached in the same way.

Biotin

Biotin, a member of the water-soluble B-complex group of vitamins, is synthesized by higher plants and most fungi and bacteria. Humans, other mammals, and birds cannot synthesize biotin *de novo* and therefore must obtain this essential micronutrient from material synthesized by intestinal microflora and from dietary sources. In mammals, absorption of biotin occurs in the small intestine. Other important sites that play a role in normal biotin physiology include the liver (the principal site of biotin utilization), kidney (the site of reabsorption of filtered biotin), and placenta (the site of

transport of biotin from the maternal circulation to the developing embryo). Biotin obtained from dietary sources exists in both free and protein-bound forms. Protein-bound biotin is digested by gastrointestinal proteases and peptidases to biocytin and biotin-containing short peptides. Biotin present in these compounds is recycled through the action of biotinidase to release free biotin.

Biotin Enzymes

Biotin enzymes are a family of enzymes ubiquitously found throughout the nature. It appears that all organisms contain acetyl CoA carboxylase, reflecting the essential role this enzyme plays in the synthesis of fatty acids required for membrane biogenesis. While some organisms, such as bacteria, possess only one biotin enzyme, other organisms have multiple biotin enzymes. For example, mammalian cells express pyruvate carboxylase, propionyl-CoA carboxylase, and methylcrotonyl-CoA carboxylase, in addition to two isoforms of acetyl-CoA carboxylase. These enzymes catalyze key metabolic reactions in gluconeogenesis and amino acid metabolism, in addition to fatty acid metabolism.

The members of this enzyme family utilize biotin as a mobile carboxyl carrier in a conserved reaction mechanism that requires three domains: a biotin carboxylase domain, a transcarboxylase (TC) domain, and a biotin domain containing the covalently attached biotin moiety. As shown in [Figure 1](#), these enzymes catalyze reactions in two partial reactions carried out at spatially separate sites on the protein where biotin itself carries a carboxyl group between the two sites. Biotin enzymes can be divided into three classes depending on the nature of the original donor and final carboxyl acceptor. These are the carboxylases (class I), decarboxylases (class II), and TCs (class III). All eukaryotic enzymes belong to class I, while prokaryotes contain enzymes from all the three classes.

The mechanism of biotin carboxylation in the class I enzymes has been extensively investigated. Experiments on propionyl CoA carboxylase and pyruvate carboxylase showed that the

Figure 1 Biotin-mediated carboxyl transfer between reaction subsites of biotin enzymes. The biotin group attached to the target lysine is shown located in the cleft of the biotin enzyme. The carboxylate anion, complexed to the biotin, is shown in the shaded circle. The arrow represents movement of the mobile cofactor between the two partial reaction subsites during catalysis. The reactions performed at the separate subsites are indicated for the three classes of biotin enzymes.

source of CO_2 in the reaction is bicarbonate and the reaction is dependent upon the presence of adenosine triphosphate (ATP):

At the first partial reaction site, biotin is carboxylated at the 1'-nitrogen probably after the formation of a very labile enzyme-bound carboxyphosphate intermediate that donates the activated carboxyl group to biotin. Although no direct evidence of this reaction mechanism has been reported, several observations suggest this as the most likely scheme. Most notable are the similarities between the biotin enzymes and carbamoyl phosphate synthetase, an enzyme known to utilize a carboxyphosphate intermediate.

Subsequently, in the second partial reaction, the transfer of the carboxyl group from carboxybiotin to the acceptor molecule occurs. It has been proposed that the decarboxylation of carboxybiotin proceeds along a pathway where CO_2 and the enolate of biotin are formed. Following protonation, carboxylated biotin can again be formed at the first reaction site under physiological conditions:

The class II decarboxylases differ from the class I carboxylases in that the reactions are ATP independent. The decarboxylases of anaerobic prokaryotes all catalyze decarboxylation of a specific β -keto acid or acyl-CoA coupled to sodium ion export against a concentration gradient. Thus, this class of enzyme serves as an important energy transducer that does not require ATP. There is only one known member belonging to the class III biotin enzymes: *Propionibacterium freudenreichii* subsp. *shermanii* TC. TC catalyzes the formation of methylmalonyl-CoA from propionyl-CoA using oxaloacetate as a carboxyl donor, and it exists as a multimeric complex composed of 30 polypeptides of three different types.

Biotin Domains

The biotin prosthetic group is covalently attached via the ϵ -amino group of one specific lysine residue within the biotin

enzymes. This biotin-accepting lysine is found in a tetrapeptide sequence, Ala-Met-Lys-Met, which is extremely conserved among all biotin enzymes (Figure 2). In addition, the primary structure surrounding the target lysine residue shows a high degree of homology between a wide range of enzymes and species (Figure 2). Deletion studies have revealed that 30–35 amino acid residues on either side of biocytin are necessary to specify biotinylation. Collectively, these structures, able to incorporate biotin *in vivo*, are termed biotin domains. The removal of determinants necessary to define the structure of a biotin domain by truncation or mutation results in a molecule that is unable to be biotinylated.

The biotin domain participates in a number of heterologous protein-protein interactions in the cell. First, it serves as a substrate in the biotinylation reaction. Here, the biotin prosthetic group is covalently attached to the biotin domain through the enzymatic action of biotin protein ligase (BPL). Subtle conformational changes to the biotin domain that occur upon biotinylation are thought to signal dissociation of the two proteins and yield the biotinylated product. The biotinylated or holo biotin domain is then free to interact with each of the two partial reaction sites in the carboxylase, shuttling carboxyl groups between substrates in the enzyme complex.

The formation of multimeric protein complexes, characteristic of all biotin enzymes, is not necessary for substrate recognition by BPLs. Enzymatic biotinylation experiments, performed using the biotin accepting subunit of the *P. shermanii* TC or the biotin carboxyl carrier protein (BCCP) of *Escherichia coli* acetyl CoA carboxylase, have shown that these domains function equally well as BPL substrates as do the intact or multimeric protein complex. Therefore, the information required for association with BPL is present within the structured biotin domain. BPLs from various sources have been found to recognize and biotinylate acceptor proteins from very different sources.

In 1966, McAllister and Coon first showed that extracts containing BPLs from rabbit liver, yeast, and *P. shermanii* were able to activate enzyme substrates from rabbit and bacteria via the attachment of the biotin prosthetic group. Evidence of cross-species recognition *in vivo* was demonstrated when the 1.3S subunit of TC was recombinantly expressed in *E. coli* and shown to be a substrate for the *E. coli* BPL. Truncation analysis of the 1.3S TC subunit revealed that the minimum amount of

Figure 2 Sequence alignment of the biotin domains of biotin carboxylases from diverse organisms. Residues forming β -strands in the three-dimensional structures of *Escherichia coli* biotin carboxyl carrier protein (BCCP) and *Propionibacterium freudenreichii* subsp. *shermanii* transcarboxylase (TC) are underlined, and hydrophobic core residues are indicated by (•). The biotinylated lysine is marked (♦). Shading indicates residues very highly conserved in all biotin domains for which sequence data are available. Reproduced from Chapman-Smith A and Cronan JE, Jr. (1999) The enzymatic biotinylation of proteins: A post-translational modification of exceptional specificity. *Trends in Biochemical Sciences* 24: 359–363.

Figure 3 Three-dimensional structures of two biotin domains. The structures of the biotin domains from the biotin carboxyl carrier protein (BCCP) of (left) *Escherichia coli* acetyl CoA carboxylase and (right) the 1.3S subunit of *Propionibacterium freudenreichii* subsp. *shermanii* transcarboxylase (TC) have been determined. The holo forms of the two proteins with the biotin moiety specifically attached to the target lysine residues at position 122 and 89, respectively, are depicted. Solid arrows represent the β -strands in the fold. The amino (N) and carboxyl (C) termini of the domain are indicated. The molecules have been orientated to highlight the interaction of biotin with the thumb structure in BCCP.

information required to specify biotinylation was present in the 75 C-terminal amino acid residues. This minimal peptide, fused to β -galactosidase, was biotinylated *in vivo* by the BPL from *E. coli*. Similarly, the C-terminal 87-amino-acid residue of BCCP (BCCP-87) was shown to be a stable protein that can function as a substrate for *E. coli*, insect, yeast, and human BPLs. Together, these studies suggest that all biotin domains fold into an essentially common tertiary structure recognized by all members of the BPL enzyme family.

Biotin Domain Structure

The structures of two biotin domains have been determined: that of the *E. coli* BCCP-87 (Figure 3) and the 1.3S subunit of *P. shermanii* TC. These proteins are structurally related to the lipoyl domains of 2-oxo acid dehydrogenase multienzyme complexes, which also undergo an analogous posttranslational modification. These domains form a flattened β -barrel

structure comprising two four-stranded β -sheets with the N- and C-terminal residues close together at one end of the structure. At the other end of the molecule, the biotinyl- or lipoyl-accepting lysine resides on a highly exposed, tight hairpin loop between $\beta 4$ and $\beta 5$ strands. The structure of the domain is stabilized by a core of hydrophobic residues, which are important structural determinants. Conserved glycine residues (Figure 2) occupy β -turns linking the β -strands.

BCCP-87 contains a seven-amino-acid insertion common to prokaryotic acetyl-CoA carboxylases but not present in other biotin domains. This region of the peptide adopts a thumb structure between the $\beta 2$ and $\beta 3$ strands and, interestingly, forms direct contacts with the biotin moiety in both the crystal and solution structures. The significance of this interaction is not understood, but structural studies on the 1.3S subunit of TC, which is a thumbless biotin domain, have revealed that biotin also interacts with the protein. Residues in the N-terminal region of the TC subunit, independent of the biotin domain, functionally compensate for the thumb structure by binding to biotin only when the cofactor is in its carboxylated state. Therefore, it is possible that the mechanism employed by the biotin enzymes may involve noncovalent interactions between the protein and the prosthetic group.

Biotin Ligase

Reaction Mechanism

All BPLs catalyze biotinylation through the same reaction mechanism:

In the first partial reaction, BPLs bind biotin and ATP in an ordered manner (depending on the species) to form an enzyme:biotinyl-5'-AMP complex or holo-BPL. At this stage, the carboxyl group of inert biotin is activated by the addition of an adenylate group forming the intermediate biotinyl-5'-AMP. In the second partial reaction, holo-BPL complexes with an apo-biotin domain. Nucleophilic attack upon the activated biotin by the amine group of the biotin-accepting lysine residue results in the transfer of biotin from the adenylate onto the biotin domain with AMP acting as the leaving group. This two-step process is analogous to the tRNA synthetase-catalyzed linkage of amino acids to the 3' hydroxyl group of tRNAs.

E. coli Biotin Ligase, BirA

The best-characterized BPL is the 35.3-kDa protein BirA from *E. coli*. This protein is a bifunctional molecule which, in addition to BPL activity, acts as the transcriptional repressor of the biotin biosynthetic operon. By combining the regulation of biotin synthesis and metabolism through the actions of a single protein, bacteria have evolved an exceptional mechanism for maintaining biotin homeostasis. Recent structural studies of BirA, together with enzymatic and genetic studies, have provided powerful insights into BirA action. The crystal structure of BirA shows that the protein is composed of three domains: a DNA-binding N-terminal domain, a central catalytic domain, and a C-terminal domain (Figure 4). The central

Figure 4 The three-dimensional structure of BirA. The diagram shows the structure of *Escherichia coli* biotin protein ligase, BirA, determined by X-ray crystallography. This figure highlights the three functional domains in the bifunctional protein. The N-terminal domain (N), shown in purple, contains a helix-loop-helix fold to facilitate DNA binding. The central catalytic domain (shown in blue) is depicted with biotin (ball and stick representation) bound at the active site. Dots represent the unstructured loops around the active site that become ordered during the reaction. The function of the C-terminal (C) domain (shown in green) is not fully understood. Modified from Chapman-Smith A, Mulhern TD, Whelan F, Cronan JE, Jr., and Wallace JC (2001) The C-terminal domain of biotin protein ligase from *E. coli* is required for catalytic activity. *Protein Science* 10: 2608–2617.

domain contains several poorly defined loops that become more ordered upon binding of biotin or biotinyl-5'-AMP. Ordering of these loops in the complex results in the generation of an extended β -sheet, which is required for the interaction with other proteins. Thus, when complexed with biotinyl-5'-AMP, BirA is competent to participate in one of the two competing interactions: either with apo-BCCP or with the 40-base-pair operator sequence within the biotin synthesis operon. In the presence of apo-BCCP, monomeric BirA preferentially interacts with this protein substrate and catalyzes biotinylation. In the absence of apo-BCCP, the BirA complex forms the homodimer structure required for DNA binding and thus functions as a transcriptional repressor. Therefore, when *E. coli* needs to produce additional active acetyl-CoA carboxylase, its biotin biosynthetic pathway can be derepressed by the expression of apo-BCCP, thereby allowing the bacteria to balance its nutritional requirements.

Glossary

Avidin A protein that binds avidly to biotin ($K_d < 10^{-15}$ M) and is found in egg whites. A related bacterial protein is streptavidin, from *Streptomyces avidinii*.

Biocytin A biotin derivative formed between biotin and lysine. It is formed by the catabolism of carboxylases, and is

itself degraded to biotin and lysine by the enzyme biotinidase.

Biotin A water-soluble vitamin that is used by carboxylases for transfer of CO₂ groups in biosynthesis. It is bound tightly by the proteins avidin and streptavidin.

The biotinylation of proteins is the covalent coupling of biotin to an amino acid or carbohydrate moiety of the protein. Biotinylation occurs in a specific group of proteins known as carboxylases. These are enzymes that are important in several metabolic pathways, including amino acid metabolism, fatty acid biosynthesis, and gluconeogenesis. Each of these carboxylases is biotinylated on a single lysyl residue through the action of a biotin:protein ligase (BPL), and are found in all organisms (bacteria, plants, and animals). Biotinylation of proteins is also done by *in vitro* chemical synthesis, whereby biotin can be covalently coupled to any reactive functional group on the protein, and is not necessarily restricted to a single amino acid residue.

Analytical and Clinical Applications

Chemically biotinylated proteins are important tools in cell biology and biochemistry, and have clinical applications. The uses of chemically biotinylated proteins have evolved from the strong interaction between biotin (and its derivatives) and avidin or streptavidin. The medical importance of biotinylated proteins is twofold: (1) Life-threatening diseases result from failure to produce adequate levels of endogenous biotinylated proteins. These diseases are particularly serious in newborns and early childhood. (2) The diagnosis and treatment of tumors has been greatly facilitated by chemically biotinylated proteins. As an analytical reagent in cell biology and biochemistry, chemical biotinylation of proteins is in widespread use not only primarily for protein detection and assay, but also for purification. These are considered in greater detail in this article.

Biosynthesis and Degradation of Natively Biotinylated Proteins

The biotinylated proteins native to cells are the biotin-dependent carboxylases: acetyl CoA carboxylase, beta-methylcrotonyl CoA carboxylase, propionyl CoA carboxylase, and pyruvate carboxylase. The first is a cytosolic protein and the latter three are in the mitochondria. In bacteria, the biotinylated protein is biotin carboxyl carrier protein which is a subunit of

bacterial carboxylases. The biosynthesis of naturally biotinylated proteins occurs in two steps. Biotin is activated by reaction with adenosine triphosphate, releasing pyrophosphate and biotinyl 5'-adenosine monophosphate. The hydrolysis of pyrophosphate makes this step essentially irreversible under physiological conditions. The transfer of biotin to an ϵ -amino group of a specific lysyl residue in the acceptor protein is catalyzed by holocarboxylase synthetase (HS) in eukaryotes and BPL in bacteria. The specific lysyl residue that is biotinylated is found within a highly conserved structural motif of the apoprotein – the biotin domain – that ranges in length from 67 to 85 amino acids. The biotin domain is an independently folding motif with a core structure of eight β -strands forming two apposing antiparallel β -sheets. Conservation of the catalytic portions of the HS/BPL enzymes and of the biotin domains are so high across evolution that bacterial BPL can recognize and biotinylate mammalian biotin domains, and mammalian HS can recognize and biotinylate bacterial biotin domains. The consensus amino acid sequence surrounding the acceptor lysyl residue is Glu-Ala-Met-Lys-Met, but only the Met-Lys-Met residues are invariant. The conservation of the methionyl residues appears to be dictated by evolutionary pressure to retain a catalytically active carboxylase rather than a recognition site for the synthetase, since Thr or Val can be substituted for these Met residues with little loss of biotinylation but more significant losses in catalytic efficiency of the biotinylated product. In general, it appears that conservation of the β -sheet structure of the biotin domain is as critical for recognition by the ligase as the consensus sequence, but the latter is governed by the need to conserve optimal enzymatic activity in the biotinylated proteins. Thus, the two aspects controlling specificity of protein biotinylation are: first, recognition by the ligase and second, enzymatic activity of the biotinylated protein. Biotinylated proteins are degraded by cellular proteases, and the biotinylated lysyl residue (biocytin) is the product of that degradation. Biotinidase is the enzyme that cleaves biocytin to biotin and lysine.

Medical Importance of Biotinylated Proteins

Diseases caused by deficiencies in the biotin-dependent carboxylases fall into two general categories based on whether biotin

Figure 1 Biotinylation of proteins by enzymatic and chemical reactions. (a) The transfer of biotin from AMP to the ϵ -amino group of a lysyl residue in a protein, catalyzed by holocarboxylase synthetase (HS) forming an amide linkage. (b) The transfer of biotin, with a hydrocarbon spacer of 'n' methylene groups from an N-hydroxysuccinimide ester (NHS) to an ϵ -amino group of a protein in water.

administration is an effective treatment. Those not treatable with biotin are due to genetic lesions in the biotin-dependent carboxylases (OMIM 200350, 210200, 232050, 232000, and 266150 which are described at the National Institutes of Health website), whereas those treatable with biotin are the result of genetic lesions in the synthetase (multiple carboxylase deficiency; OMIM 253270) or biotinidase (OMIM 25360). Clinically, the synthetase and biotinidase deficiencies are distinguished by the early (up to 3 months postpartum) versus late onset of symptoms, respectively. Mutations in holocarboxylase generally cause a raised Michaelis constant for biotin. Thus, the treatment with pharmacological doses of biotin is probably successful because the enzyme only requires higher concentrations of biotin for efficient biotinylation of the apoprotein carboxylases. The success of biotin administration when biotinidase is lost indicates the biological importance of recycling biotin from biocytin to maintain sufficient levels of carboxylase activity. The other clinically significant aspect of biotinidase is its ability to degrade radiolabeled biotin derivatives, which are used in conjunction with biotinylated antibodies to image and/or treat tumors.

Chemical Synthesis of Biotinylated Proteins

The usual goal of protein biotinylation is to detect the modified protein with avidin, where the avidin is itself linked to a reporter group (a radionuclide, chromophore, fluorophore, or an enzyme). The detection of biotinylated proteins has been important in Western blots in order to determine the expression of proteins in diverse cells exposed to different stimuli or growth conditions, for the immunocytochemical and immunohistochemical localization of proteins within subcellular compartments or in tissues, and for the identification and tracking of surface-biotinylated proteins. In addition, the immobilized avidin (and derivatives) can be used for affinity capture and purification of biotinylated proteins, or in the capture of receptors using biotinylated ligands. Biotinylation of proteins can be achieved through covalent attachment of a biotin derivative to any freely reactive functional group on a protein. The most commonly used sites include primary amines

(α - or ϵ -amino groups of the N-terminal or lysyl residues, respectively, as illustrated in Figure 1(b)), thiol groups (of cysteinyl residues), and carbohydrate groups. The reactive derivatives of biotin for these reactions use N-hydroxysuccinimide esters, iodoacetyl, or disulfide derivatives of biotin, and hydrazide derivatives of biotin, respectively. The critical factor in the useful biotinylation of proteins is allowing avidin to bind the biotinyl group after conjugation. This requires sufficient distance between the surface of the biotinylated protein and avidin, since biotin is bound in a fairly deep pocket in avidin. This problem was solved by Klaus Hofmann, who found that an ϵ -aminocaproyl group offered a sufficiently long spacer group for this purpose, as illustrated in Figure 1. The use of sulfo-N-hydroxysuccinimidyl-esters (sulfo-NHS esters) for biotin derivitization introduced by James Staros further simplified the use of biotin derivatives because it increased the water solubility and amine specificity of the reactive ester. Importantly, the sulfo-NHS esters cannot cross cell membranes, and this permits the selective labeling of cell-surface proteins through biotinylation of their extracellular domains.

Clinical Application of Biotinylated Antibodies

Clinically, biotinylated antibodies are in current use for the detection and treatment of tumors, with success in many cases. The multistep procedure can be summarized as follows: biotinylated antibodies against a tumor-specific antigen are introduced into circulation. Binding to the antigen concentrates the biotinylated antibody at the site of the tumor. Avidin or streptavidin is introduced, which binds the pretargeted antibody. Because these are tetramers, at least one biotin-binding site is expected to remain unoccupied in the avidin:biotinylated antibody complex. A biotin derivative that chelates a radionuclide is then introduced, which is trapped by the open biotin-binding sites on avidin at the site of the tumor. This protocol can be used to visualize the tumor *in vivo* by immunoscintigraphy or positron emission tomography. With the appropriate radionuclide, radiotherapy of the tumor is also achievable. In such protocols, circulating biotinidase plays a counterproductive role, since it can and does break down biocytin

analogs. Thus, knowledge of the biotin cycle of endogenously biotinylated proteins has been important in the clinical application of chemically synthesized biotinylated proteins.

Glossary

Bone morphogenetic proteins A family of secreted ligands originally identified by their ability to induce ectopic bone formation which have since been shown to have diverse functions during embryonic development and tissue homeostasis.

Clade A group of genes that are related to a common ancestral gene.

Co-receptors A cell-surface receptor that binds to a signaling molecule (BMP ligand or receptor) in addition to

the primary receptors (type I and II receptors) to promote ligand recognition and/or receptor activation.

Ortholog Homologous genes that are found in different species.

SMAD A family of intracellular proteins that mediate canonical signaling from TGF- β superfamily of receptors to the nucleus. SMAD proteins are the mammalian orthologs of the *Caenorhabditis elegans* protein, SMA, and the *Drosophila* protein, Mothers Against Decapentaplegic, MAD (the name SMAD is a combination of SMA and MAD).

Bmp Signaling

Bmp Family of Ligands

Bone morphogenetic proteins (Bmps) are secreted transforming growth factor-beta (TGF- β) superfamily ligands first identified in extracts from bone matrix that could induce ectopic bone formation when implanted subcutaneously in rats. It is now known that Bmps play essential roles in the development of nearly all vertebrate organs, including the embryonic vasculature. Within the TGF- β superfamily, Bmp ligands (some of which are also referred to as growth and differentiation factors (Gdfs)) can be organized into clades based on sequence similarity to conserved molecules in primitive organisms (Figure 1). This helps to understand differences in receptor binding and cellular responses between Bmps and other ligands within this family. On this basis, 15 *bona fide* mammalian Bmp/Gdf ligands have been identified and shown to activate typical Bmp-dependent responses. Some of these responses are context dependent. For example, the more distantly related Gdf15 group of ligands can not only activate Bmp-dependent responses but also act as inhibitors of Bmp signaling in a context-dependent fashion. Other ligands such as Gdf8, Gdf11, Gdf1, and Gdf3 are misnamed since they activate pathways more typical of the TGF- β /activin ligands, while others such as Bmp3 (and inhibin) should be classified as Bmp antagonists, since they act by sequestering inactive Bmp receptor signaling complexes.

Regulation of Bmp ligand expression

Secretion of Bmp ligands is regulated at a variety of levels. Transcription of *Bmp2*, *Bmp4*, *Bmp5*, and *Gdf6* messenger RNA (mRNA) is regulated by long-range, modular tissue-specific *cis*-regulatory elements within their genomic loci. RNA expression is also regulated by gene-specific posttranscriptional regulation of mRNA stability. Secretion of mature Bmps is dependent on correct intracellular cleavage of pro-domains. This is regulated in a tissue-specific manner, indicating that secretion of biologically active ligands is regulated independently of their mRNA expression. Unlike TGF- β s, the cleaved pro-domain of most Bmps dissociates as the mature ligand

is secreted. However, Bmp7 and Bmp9 are secreted as stable complexes with their cleaved pro-domains which regulate extracellular matrix interactions, or independently activate Bmp receptors. These regulatory mechanisms have implications for studying the role of Bmp ligands in the vasculature, and reinforce the need to evaluate mature protein expression where possible (although there is a dearth of reliable antibodies that can detect tissue expression of mature Bmp ligands *in vivo*).

Extracellular Regulation of Bmp Ligands

Most Bmp ligands are secreted as biologically active dimers. These regulate local cellular responses, but a number of biologically active ligands are also detectable at nanogram per milliliter concentrations in the circulation (including Bmp4, Bmp6, and Bmp9). Given their close association with endothelial cells (ECs), these may play a role in maintaining vascular homeostasis. A number of Bmp antagonists and other non-receptor-binding proteins regulate long-range effects of Bmp ligands. These include Bmp antagonists Noggin, Twisted gastrulation (Tsg), Follistatin, and members of the Chordin and DAN family of proteins. In addition, membrane-associated heparan sulfite proteoglycans and components of the extracellular matrix, including type IV collagen, fibrillin and matrix Gla-protein, interact with and modify specific Bmp ligand activity in a context- and concentration-dependent manner. The mechanisms by which these extracellular factors regulate Bmp signaling have been extensively investigated during embryonic development, where spatiotemporal control of Bmp gradients plays a critical role in controlling developmental patterning. Many of these proteins are also expressed in the adult, and are likely to play a role in regulating Bmps expressed in the vasculature. However, there are little data on the extracellular regulation of Bmps in the adult.

These proteins inhibit Bmp activity by sequestering ligands away from their receptors, reducing free movement in the extracellular space and/or promoting endocytic uptake and degradation of the ligands. Ligands bind with varying affinity to these inhibitors. For example, Noggin binds to Bmp2,

Figure 1 Phylogenetic comparison of TGF- β superfamily ligands based upon full-length human protein sequences. Sequence similarity to *Drosophila* Bmp orthologs is indicated. Alternative names are listed in parentheses. Ligands in blue are *bona fide* Bmps that have been shown to activate Bmp Smads. Reproduced from Lowery JW and de Caestecker MP (2010) BMP signaling in vascular development and disease. *Cytokine and Growth Factor Reviews* 21: 287–298.

Bmp4, Bmp7, and Gdf5 with high affinity but does not inhibit Bmp9 or 10 activity at all. Chordin binds to Bmp2, Bmp4, and Bmp7 but does not interact with other Bmp family members. These effects are more complex in the intact organism where different binding proteins interact. For example, Tsg forms a tri-molecular Chordin/Bmp/Tsg complex that inhibits Bmp4 by stabilizing Chordin–Bmp interactions. However, Tsg also enhances Bmp signaling by promoting cleavage of Chordin from the Chordin–Bmp complex by the protease Bmp1/Tolloid. (Bmp1 was identified as part of the original screen for bone matrix-derived extracts with bone-inducing activity, but is not a member of the Bmp family.) This sets the stage to establish a gradient of Bmp activity where high concentrations of Chordin antagonize Bmp activity, while relative excess of Tsg releases Bmp from the Chordin complex and activates of Bmp signaling. Bmper/Cv2 also inhibits Bmp4 at high concentrations (promoting endocytic uptake and degradation), but activates Bmp signaling at low concentrations (facilitating

ligand interaction with receptors). This phenomenon whereby Bmp-binding proteins can activate Bmp signaling in a context- and concentration-dependent fashion has implications for investigators exploring the mechanisms by which Bmps have different short- and long-range effects on the vasculature.

Bmp Receptors

Signal transduction is initiated by binding to receptors and formation of heterotetrameric complexes comprising combinations of type 1 (activin-like kinases (Alk) 1/2/3 and 6) and type 2 Bmp receptors (Bmpr2, Actr2a, and Actr2b). Both types of receptors have extracellular ligand binding, transmembrane and cytoplasmic serine/threonine kinase domains. Proximity of the type 2 receptor kinase domain with the type 1 receptor occurs upon ligand-induced oligomerization and promotes phosphorylation of serine and threonine residues in the GS box N-terminal to the kinase domain of the type 1 receptor.

This alters conformation of the type 1 receptor, activating the kinase by allowing adenosine triphosphate (ATP) to enter the kinase pocket. Bmpr2 is unique in having a long C-terminal tail that may regulate Bmp-dependent responses by promoting degradation of the Smad ubiquitin ligase, Smurf1. Tail domain interactions with cyclic guanoside monophosphate-dependent kinase 1 and LIM kinase 1 may also enhance downstream responses to Bmps. In general, however, the activated kinase domain of type 1 Bmp receptors phosphorylates and activates a subclass of signaling intermediates, the Bmp-activated Smads (Smad1, Smad5, and Smad8). This distinguishes the TGF- β /activin-activated type 1 receptors (Alk4, Alk5, and Alk7) which activate a different class of Smads (Smad2 and Smad3).

Bmp ligand–receptor interactions

Bmp type 1 receptors are divided into two groups based on sequence similarities: Alk3/6 and Alk1/2. These have distinct ligand-binding properties (Table 1) but show promiscuity in binding to different members of the TGF- β superfamily. Alk3 and Alk6 interact with and are activated by Bmp2 and 4 equally, while Bmp5–8 group ligands principally activate Alk2. Bmps also have different affinities for type 1 and type 2 receptors. Bmp2 and 4 bind to Alk3 and 6 but only recruit type 2 receptors, Bmpr2, Actr2a, and/or Actr2b once bound to these type 1 receptors. In contrast, Bmp5–8 group ligands bind with high affinity to Actr2a and Actr2b and subsequently recruit type 1 receptors into active signaling complexes. Bmp9 behaves like Bmp2/4 and Bmp5–8 in different cells: it binds directly to Alk1 in ECs but only interacts with Alk2 in the presence of type 2 receptors in other cell types. Some Bmps, such as Gdf9, interact with Bmpr2, and also recruit the TGF- β receptor Alk5 into active signaling complexes. Moreover, TGF- β can recruit Alk1, Alk2, and Alk3 into heteromeric complexes with the type 1 TGF- β receptor Alk5. This accounts for the coincident activation of Smad1/5/8 and Smad2/3 by TGF- β in a variety of cell types. Different TGF- β ligands may also exert opposing effects by signaling through the same receptors. Bmp9 also activates Alk1 in ECs, but, unlike TGF- β /Alk1, this sustained Smad1/5/8 signal exerts anti-angiogenic effects in ECs. In addition, while Bmpr2 only interacts with Bmp family members, Actr2a and Actr2b interact with activins, Gdf8 and Gdf11, which recruit TGF- β /activin type 1 receptors into signaling complexes. This inhibits Bmp responses by sequestering type 2 receptors that also interact with Bmp ligands. Some TGF- β family ligands, including Bmp3 and inhibin, also inhibit Bmp signaling by sequestering type 2 receptors without activating downstream signals. Furthermore, Gdf9b(Bmp15), which activates Bmp-Smads in granulosa cells, inhibits Smad phosphorylation in other cell types by forming complexes with Bmp4 and likely inhibiting receptor binding. This context-dependent inhibitory function is shared by Bmps that lack a cysteine residue required for ligand dimerization, including Gdf9 and Gdf3. Bmp ligands can also be secreted as hetero-dimers; presenting dual ligand-receptor binding sites that promote higher receptor binding affinities and/or recruit more complex assemblies of Bmp receptors. Studies in Zebrafish embryos show that Bmp2 and 7 form heterodimers when over-expressed at physiologically relevant concentrations. These recruit and activate heteromeric complexes of type 1 Bmp receptors Alk3 and Alk8 (Alk8 is the Zebrafish orthologue of Alk2). It remains to be established

Table 1 Demonstrated type I and type II receptor interactions for *bona fide* Bmp ligands

		Bmp4 (Bmp2B)

Alternative names are listed in parentheses.

whether Bmps are actually secreted as heteromeric ligands endogenously (due to lack of effective reagents). However, these experiments provide insight into the diversity of receptor usage by Bmps *in vivo*.

Bmp Co-Receptors

A number of membrane-associated co-receptors have been identified, including the repulsive guidance molecule (RGM) family, betaglycan, and endoglin, which enhance Bmp signaling by modifying Bmp ligand–receptor interactions (Table 2).

Table 2 Co-receptors of BMP signaling

Co-receptor	Partner
Endoglin (CD105)	Bmp2 (Bmp2A) Bmp7 (OP-1) Bmp9 (Gdf2)
TGF β R3 (betaglycan)	Bmp2 (Bmp2A) Bmp4 (Bmp2B) Bmp7 (OP-1) Gdf5 (Bmp14)
RGMa	Bmp2 (Bmp2A) Bmp4 (Bmp2B) Gdf7 (Bmp12)
RGMb (DRAGON)	Bmp2 (Bmp2A) Bmp4 (Bmp2B) Gdf7 (Bmp12)
RGMc (hemojuvelin)	Bmp2 (Bmp2A) Bmp4 (Bmp2B) Bmp6 (Vgr1) Gdf7 (Bmp12)
Bambi (Nma)	Alk1 Alk3 Alk6 Actr2
TrkC	Bmpr2
Ror2	Alk6 (Bmpr1B)

Alternative names are listed in parentheses.

In addition, the type 1 TGF- β family pseudo-receptor Bambi/Nma interacts with a number of type 1 and 2 Bmp receptors, and is thought to inhibit Bmp signaling by interfering with the assembly of activated receptor signaling complexes. However, *Bambi* knockout mice do not have any obvious developmental defects, suggesting that these inhibitory effects are likely to be minor *in vivo*.

Betaglycan/TGF β R3 and endoglin/CD105 are related transmembrane proteoglycans that also modify Bmp-receptor interactions. Both have large extracellular domains and short cytoplasmic tails lacking kinase activity. Endoglin and betaglycan undergo proteolytic cleavage, with the soluble extracellular domain being released into the extracellular space and antagonizing the effects of the membrane-associated co-receptors. Soluble endoglin and betaglycan are detected in the circulation both normally and in disease states.

Betaglycan

Betaglycan is ubiquitously expressed and is the major cell surface TGF- β -binding protein, and also interacts with Bmp2, Bmp4, Bmp7, Gdf5, and inhibin. The classical mechanism by which betaglycan enhances Bmp signaling is by increasing Bmp ligand binding to Alk3 and Alk6. However, betaglycan also inhibits Bmp2 and Bmp7 signaling by sequestering Bmpr2 and Actr2 into inactive complexes containing inhibin, and enhances Bmp signaling through its ability to regulate trafficking and cell localization of interacting receptors. For example, through its interaction with the scaffolding protein, β -arrestin2, betaglycan binds to and promotes internalization of Alk6, thereby selectively enhancing Alk6-dependent signaling.

Endoglin

Endoglin is dominantly expressed in ECs, but, like betaglycan, it interacts with other TGF- β family ligands, including Activin A, Bmp2, Bmp7, and Bmp9. Most of these interactions are dependent on the presence of the respective ligand binding TGF- β superfamily receptors, with the exception of Bmp9, with which it can bind directly. These interactions are required for TGF- β to activate Alk1-Smad1/5 but inhibit Alk5 signaling in ECs. Endoglin also enhances Bmp7 and Bmp9-dependent Smad1/5 responses, although the mechanism by which this occurs is largely unknown. Endoglin does not enhance nor is it required to generate type 1/type 2 receptor complexes. However, Alk5 phosphorylates the cytoplasmic tail of endoglin and this is required for endoglin to activate both TGF- β and Bmp9-dependent Alk1 signaling in ECs, suggesting that the cytoplasmic tail plays an essential role in activating Alk1-signaling. This may be of significance in vascular disease since there is increased expression of S-endoglin, a splice variant that lacks this cytoplasmic tail, in senescent ECs, and transgenic over-expression of S-endoglin promotes endothelial dysfunction.

RGM/DRAGON family of Bmp co-receptors

The RGM GPI-anchored proteins RGMa, RGMb/Dragon, and RGMc/HJV, originally identified as regulators of axonal guidance, are widely expressed outside the nervous system and bind to a number of Bmps. All three RGMs interact with Bmp2, Bmp4, and Gdf7 and enhance Smad1/5 signaling. RGMc undergoes proteolytic cleavage, releasing a soluble form that inhibits the membrane-associated co-receptor. Unlike RGMa, membrane-associated RGMc activates Bmp6-dependent responses and plays an essential role in regulating Bmp6-dependent control of iron metabolism *in vivo*. The mechanism by which RGMs enhance Bmp signaling is unclear. RGMa increases binding of Bmp2 to Alk3 and Actr2a, while both RGMa and RGMc increase utilization of Actr2a by Bmp2 and Bmp4 in the presence of Bmpr2. This suggests that RGMs modify the composition of activated receptor complexes by altering binding affinities of Bmp ligands for their receptors.

Smad Signaling

GS box phosphorylation of the type 1 receptor kinase increases affinity of the type 1 receptor for its Smad substrate and promotes phosphorylation of a conserved SXS motif at the C-terminus of receptor activated Smads (RA-Smads). This requires trafficking into early endosomes where the type 1 receptor encounters SMAD anchor for receptor activation (SARA) and Hgs (which recruit Smad2 to Alk5), or endofin (which recruits Smad1 to Alk3 and Alk6). Phosphorylation of RA-Smads destabilizes RA-Smad-SARA/endofin interactions, exposing nuclear import sequences in the Smad N-terminus. SXS motif phosphorylation also increases RA-Smads affinity for Smad4, giving rise to heteromeric RA-Smad/Smad4 complexes that translocate to the nucleus and activate transcriptional responses. Smad4 is required for most, but not all, Smad-dependent responses. Signaling specificity is determined by sequences in the L45 loop of the type 1 receptors. Invariant sequences in the L45 loop of Alk4/Alk5 and Alk7 interact with conserved sequences in the C-terminus of Smad2/3, while distinct L45 loop sequences in Alk3/6,

and Alk 1/2, interact with conserved residues in Smad1/5/8. This paradigm holds true in many contexts. However, recent studies indicate that TGF- β -induced activation of Smad1/5/8 is not always dependent on Bmp type 1 receptors, but can result from recruitment of Smad1/5/8 to activated TGF β R2/Alk5 complexes. Conversely, while the mechanisms remain unclear, both Bmp2 and 9 can phosphorylate and activate Smad1/5/8 and Smad2. This indicates that while the two-pathway model of Smad signaling is widely applicable, the Bmp versus TGF- β signaling paradigm is not as straightforward as originally thought.

Regulation of Smad signaling

The duration and intensity of Smad signaling are regulated at a number of different levels. Caveolar-mediated endocytosis and association with inhibitory Smads (I-Smads: Smad6 and Smad7) promote proteosomal degradation of Bmp and TGF- β receptor complexes and RA-Smads by Smad ubiquitin ligases Smurf1 and Smurf2. I-Smads are up-regulated by TGF- β and Bmps, thus providing feedback inhibition. Smad6 inhibits Bmp signaling by selectively interacting with Alk1, Alk2, Alk3, and Alk6, while Smad7 lacks type 1 receptor specificity and inhibits both Bmp and TGF- β responses. Smad signaling is also regulated by type 1 receptor de-phosphorylation. For example, PP1 is recruited to activated receptors by SARA and endofin, promoting receptor de-phosphorylation. In the nucleus, the phosphatases Ppm1A and Scp1-3 de-phosphorylate RA-Smads. This dissociates RA-Smad/Smad4 complexes, exposing nuclear export signals and enables recycling of Smad4 and RA-Smads to the cytoplasm. Other posttranslational modifications, including sumoylation, mono-ubiquitination, and acetylation, regulate nucleocytoplasmic shuttling of TGF- β -activated Smad2/3, but it is unclear whether they regulate Bmp signaling. In addition, a number of kinases regulate Smad activity by phosphorylating the linker and N-terminal domains of RA-Smads. Epidermal growth factor (EGF)- and fibroblast growth factor-induced extracellular signal regulated kinase (ERK) mitogen-activated protein kinase (MAPK) activation and ultraviolet (UV)-induced activation of p38 MAPK and JUN N-terminal kinase (JNK) promote phosphorylation of serine residues in the Smad1 linker. This inhibits Smad1 activity by preventing nuclear import and promoting Smurf1-dependent Smad degradation. Some of these phosphorylation events activate Smad signaling: Smad2 phosphorylation induced by hepatocyte growth factor and EGF stimulates Smad activity, while serotonin phosphorylates and activates Bmp-dependent Smad1/5 in vascular smooth muscle cells (VSMCs). Moreover, linker phosphorylation of C-terminally phosphorylated Smad1 by cyclin-dependent kinases CDK8 and CDK9 recruits YAP1 to the Smad1/Smad4 complex and enhances transcription. On this basis, sequential phosphorylation of Smads provides a mechanism by which different signaling pathways can limit (or enhance) the duration and intensity of Smad signaling.

Smad-dependent transcriptional responses

Once in the nucleus, the RA-Smad/Smad4 complexes activate transcriptional responses directly by binding to Smad-binding elements (SBE), or indirectly through interactions with DNA-binding transcription factors. DNA binding affinity is relatively weak, so recruitment of Smad complexes often depends on

synergistic interactions with other transcription factors. Given the diversity of transcriptional binding partners, this allows for cross-talk with a variety of signaling pathways. For example, Bmp-dependent target gene activation by Smad1/Smad4 is activated by β -catenin (mediator of Wnt responses) when recruited to Lef1 DNA-binding transcription factor. Similarly, Smad1 interaction with Notch intracellular domain (NICD) recruits Bmp-Smads to the RBP-Jk binding site (mediator of Notch responses) in the Herp2 promotor, thereby synergistically activating a Notch target gene in ECs.

In addition to these direct effects of Smad proteins on gene transactivation responses, there is evidence that Smad proteins can activate transcription by regulating histone modifications and reorganizing chromatin structure. *In vitro* transcription studies indicate that Smad-dependent transcription only occurs on chromatin templates. Moreover, Smads acetylate histones by recruiting histone acetyl transferases, CBP and p300, and repress transcription by recruiting repressor complexes with histone deacetylase (HDAC) activity. For example, Bmp-Smads interact with Evi-1 which recruits an HDAC complex to transcriptional targets. Bmp-Smads also recruit the co-repressor Ski to promoters, disrupting Smad interaction with CBP and p300 and recruiting a repressor complex containing HDAC1. Since expression of Smad-binding repressors is regulated, RA-Smads have the capacity to activate or repress transcription depending on availability of these co-repressor molecules.

Nontranscriptional Smad-dependent responses

Recent studies indicate that Bmp and TGF- β activated Smads regulate microRNA processing by directly interacting with Drosha complexes. Bmp signaling has also been shown to regulate transcription of a variety of microRNAs. However, unlike these Smad-dependent transcriptional responses, regulation of microRNA processing is Smad4-independent. This pathway is of importance since microRNA processing is required for their nuclear export and function, and there is evidence that a single mature microRNA can regulate expression of hundreds of proteins. This mechanism has recently been shown to play an essential role in regulating Bmp-dependent VSMC differentiation.

Smad-Independent Signaling

Different limbs of the MAP kinase (ERK, p38 MAPK, and JNK), PI3 kinase/AKT, and PKC signaling pathways, and a variety of Rho-GTPases (direct regulators of cytoskeletal dynamics), can also be activated by Bmps in a context-dependent fashion. Some of these responses require Smad-dependent transcription. Others occur rapidly, are Smad-independent, and result from signaling directly downstream of Bmp receptors. This is supported by the observation that Dorsomorphin, a small molecule inhibitor of Bmp type 1 receptor kinases, inhibits Smad1/5 activation but has no effect on Bmp-induced p38 MAPK phosphorylation in VSMCs. Activation of Smad versus non-Smad-signaling is dependent on the order of Bmp receptor assembly. Over-expression studies indicate that, unlike TGF- β receptors, Bmp receptors can form heteromeric complexes in the absence of ligand. These preformed receptor complexes (PRCs) activate Smad-dependent responses following treatment with Bmp ligands, while Bmp-induced signaling

complexes (BISCs) preferentially activate non-Smad-dependent responses (p38 MAPK in these studies). Moreover, deletion of the C-terminal tail of Bmpr2 interferes with formation of PRCs, suggesting that the Bmpr2 tail may play a role in promoting Bmp-Smad signaling. The mechanism by which these complexes promote selective Smad versus non-Smad-dependent responses is unclear. Furthermore, given the paucity of reagents to study endogenous Bmp receptor behavior, it is unknown whether PRCs occur endogenously, or whether they represent an artifact of protein over-expression.

Links between Smad-independent responses and Bmp receptors are poorly understood. Some are dependent on which type 1 and type 2 receptors are engaged. For example, Bmp-dependent activation of the Rho GTPase Cdc42 regulates cytoskeletal dynamics by phosphorylation of cofilin (promoting actin polymerization). This is dependent on interaction of Limk1 (a cofilin kinase) with the C-terminal tail of Bmpr2. In addition, Bmp7-dependent activation of PI3 kinase in cultured monocytes is dependent on expression of Bmpr2 and Actr2a but not Actr2b. One of the better-characterized Smad-independent pathways is mediated by the MAPK activators TAK1 and TAB1. TAK1 and TAB1 are required to mediate TGF- β and Bmp-dependent activation of p38 MAPK and JNK, and associate with Alk3 through an adaptor protein XIAP. However, TAK1 has also been shown to interact with Bmp-Smads and induces activating SXS phosphorylation of Smad1/5/8 (but not TGF- β activated Smad2/3). This indicates that TAK1 has distinct functions in regulating both branches of the Bmp signaling pathway, and suggests an alternative mechanism by which Bmp signaling activates Smads.

Bmp Signaling in Vascular Development and Disease

Bmp ligands, inhibitors, receptors, and downstream signaling intermediates show distinct patterns of regulation during vascular development and disease. However, given the complex nature of this signaling pathway, definitive functional data based on *in vivo* genetic data are essential to understand the functional implication of these changes. The second part of this article outlines the results of these studies from a molecular rather than a disease-oriented perspective, focusing on selective molecular components of the Bmp signaling pathway that have been properly evaluated *in vivo*. We draw parallels between defects in different vascular beds, stages of development, and adult disease resulting from mutations in different components of the Bmp signaling pathway. We have summarized the relevant vascular phenotypes of humans and mice carrying defined mutations of Bmp pathway components in [Table 3](#).

Bmp Ligands

A number of Bmps have pro- or anti-angiogenic effects, and are up-regulated at sites of atherosclerosis and vascular injury. This suggests that Bmps could play a role in regulating normal vascular homeostasis and disease-associated vascular pathology. Despite these observations, the functional roles of these ligands in the intact vasculature are largely unknown.

Bmp2 and Bmp4

Bmp2 and Bmp4 are up-regulated in ECs at sites of systemic vascular injury and in atherosclerotic plaques. Moreover, Bmp2 is up-regulated in vessel walls in two different rat models of systemic hypertension. The effects of these changes in Bmp expression are impossible to predict based on the results of *in vitro*, cell culture studies alone. For example, while it has been shown that Bmp2 and Bmp4 inhibit serum and platelet-derived growth factor-induced proliferation of aortic VSMCs, others have shown that the same ligands enhance proliferation of aortic VSMCs. Furthermore, while Bmp2 and Bmp4 increase expression of VSMC differentiation markers in human aortic VSMCs, others have shown that Bmp2 (but not Bmp4) down-regulates expression of the same differentiation markers in rat aortic SMCs. These contrasting findings reflect the heterogeneity of cultured vascular cells and the effects of passage number on cell differentiation. For these reasons, and given the complex and integrative nature of the Bmp signaling pathway *in vivo*, we believe that functional effects of these ligands can only properly be evaluated in the intact organism.

There are no data on the effects of genetic manipulation of Bmp ligand expression on the systemic vasculature *in vivo*. However, over-expression of Bmp2 induced using an adenoviral delivery system reduces neointimal proliferation following carotid artery balloon injury in rats. This suggests that Bmp2 may have protective effects in atherosclerotic plaque formation. Conversely, continuous subcutaneous infusion of Bmp4 in mice promotes systemic hypertension, and is associated with impaired EC-dependent vasodilatation in aortic ring preparations. The latter effects are dependent on Bmp4 induction of reactive oxygen species (ROS) in ECs, and are consistent with the observation that exogenous Bmp2 induces ROS and inhibits EC-dependent vasodilatation in rat carotid artery rings. Moreover, both Bmp2 and Bmp4 increase EC adhesiveness to circulating inflammatory cells in an ROS-dependent fashion. These findings suggest that Bmps not only influence vascular cell proliferation and/or differentiation but also influence vascular reactivity and inflammatory responses. These effects may be dependent on the vascular bed, since Bmp4 has been shown to inhibit EC-dependent vasodilatation in carotid and coronary but not pulmonary artery preparations.

Pulmonary Bmp2 and Bmp4 expressions are strongly up-regulated in a model of chronic, hypoxia-induced pulmonary hypertension (PH). This model is characterized by sustained increases in pulmonary vascular resistance associated with increased peripheral pulmonary vascular remodeling. Bmp4 displays a wide expression pattern in alveolar and bronchial epithelium, while Bmp2 is largely expressed in the peripheral resistance vessels of the pulmonary vasculature following exposure to hypoxia. These vessels are the primary site of pulmonary vascular remodeling and resistance in hypoxic PH, suggesting that local expression of Bmp2 and Bmp4 may have different effects on the pulmonary vasculature in hypoxic PH. However, *in vitro* studies provide conflicting reports about the effects of Bmps on pulmonary vascular cells. For example, Bmp4 inhibits proliferation and promotes apoptosis in proximal pulmonary artery VSMCs, but increases proliferation and inhibits apoptosis in VSMCs derived from more peripheral vessels. Moreover, Bmp4 promotes proliferation in early-passage mouse proximal

Table 3 Vascular phenotypes of Bmp mutations in humans (all capital letters) and mice

Genetic modification	Het/homozygous	Vascular phenotype	Survival
<i>Bmp2</i> null	Heterozygous	Susceptible to hypoxic PH	Viable
<i>Bmp4</i> null-LacZ	Heterozygous	Less severe hypoxic PH, impaired vascular remodeling	Viable
<i>Bmpr2</i> null	Heterozygous	Susceptible to PH, defective vascular remodeling, abnormal vascular tone	Viable
<i>Bmpr2</i> hypomorph (Δ Ex2)	Heterozygous	Susceptible to hypoxic PH; endothelial dysfunction and abnormal vascular tone	Viable
<i>Bmpr2</i> knockdown	90% knockdown by RNAi	Hemorrhage; vascular dysplasia; impaired VSMC recruitment	Viable
<i>Bmpr2</i> conditional	Pulmonary EC	Spontaneous PH, vascular inflammation	Viable
<i>BMPR2</i> (mis-sense, nonsense)	Heterozygous	HPAH, HPAH with HHT	Viable
<i>Alk1</i> null	Homozygous	Angiogenesis defects, impaired VSMC recruitment	Lethal (E10.5)
	Heterozygous	Models HHT	Viable
<i>Alk1</i> conditional	EC-specific	Vascular dysplasia	Viable
<i>ALK1</i> (mis-sense, nonsense)	Heterozygous	HHT2, HPAH with and without HHT2	Viable
<i>Alk3</i> conditional	Mesoderm deletion	Hemorrhage, cardiac defects, impaired VSMC recruitment	Lethal (E10.5)
	SMC (embryo)	Cardiac defects, hemorrhage, impaired vascular remodeling	Lethal (E11.5)
	SMC (adult)	Impaired vascular remodeling	Viable
<i>Endoglin</i> null	Homozygous	Angiogenesis defects	Lethal (E10.5)
	Heterozygous	Models HHT, spontaneous PH, abnormal vascular tone	Viable
<i>ENDOGLIN</i> (mis-sense, nonsense)	Heterozygous	HHT1, HPAH with HHT1	Viable
<i>Smad1</i> null	Homozygous	Defects in fusion of the chorioallantoic membrane and (minor) yolk sac angiogenesis	Lethal (E9.5)
<i>SMAD1</i> (mis-sense)	Heterozygous	HHT	Viable
<i>Smad4</i> conditional	EC	Cardiac and angiogenesis defects, VSMC recruitment	Lethal (E10.5)
<i>SMAD4</i> (mis-sense, nonsense)	Heterozygous	HHT (with and without JP)	Viable
<i>Smad5</i> null	Homozygous	Cardiac and angiogenesis defects	Lethal (E9.5)
<i>Smad6</i> null	Homozygous	Cardiac defects, vascular calcification, systemic hypertension	Some viable
<i>Smad8</i> null-LacZ	Homozygous	Spontaneous pulmonary vascular remodeling	Viable
<i>SMAD8</i> (nonsense)	Heterozygous	HPAH	Viable
<i>Tak1</i> null	Homozygous	Angiogenesis/cardiac defects	Lethal (E10.5)

All mutations are global unless noted otherwise.

Embryonic lethality is indicated in parenthesis as day post-coitum.

PH, pulmonary hypertension; VSMC, vascular smooth muscle cell; EC, endothelial cell; HPAH, heritable pulmonary arterial hypertension; HHT, hereditary hemorrhagic telangiectasia; VSMC, vascular smooth muscle cell; JP, juvenile polyposis.

pulmonary VSMCs but has the opposite effect on late-passage VSMCs. Given the complexity and heterogeneity of these *in vitro* responses therefore, we have taken a genetic approach to evaluate the functional role of these ligands in the intact vasculature.

Heterozygous null *Bmp2* and *Bmp4* mice show a blunted *Bmp2* and *Bmp4* response to hypoxia. However, while *Bmp2*-deficient mice have increased susceptibility to hypoxic PH, *Bmp4* deficiency partially protects against the development of hypoxic PH. In addition, while *Bmp4*-deficient mice have reduced pulmonary VSMC proliferation and peripheral vessel remodeling, there is no change in VSMC proliferation or peripheral vessel remodeling in hypoxic *Bmp2*-deficient mice. This suggests that hypoxia-induced *Bmp4* expression has distinct effects on pulmonary VSMC proliferation and remodeling while *Bmp2* does not. Moreover, hypoxic *Bmp2* but not *Bmp4*-deficient mice have reduced pulmonary endothelial nitric oxide synthase (eNOS) expression and activity (phospho-S239 VASP expression), suggesting that hypoxia-induced *Bmp2* may reduce pulmonary vascular resistance by increasing EC production of nitric oxide in small intrapulmonary resistance vessels. However, since both *Bmp2* and *Bmp4* induce eNOS expression in ECs, these findings suggest that the opposing effects of *Bmp2* and

Bmp4 in hypoxic PH result from their dominant effects on different cell types (*Bmp4* on VSMCs and *Bmp2* on ECs). Given their distinct spatial expression patterns, opposing effects of *Bmp2* and *Bmp4* are likely to result from differences in access of these ligands to distinct vascular cells types in the hypoxic lung.

Circulating Bmp ligands

In addition to local tissue production of Bmp ligands, high (ng ml⁻¹) concentrations of biologically active *Bmp4*, *Bmp6*, and *Bmp9* have been found in human serum. These biologically active ligands would have direct access to the systemic and pulmonary vascular beds, suggesting that they could play a role in maintaining normal vascular homeostasis. Unlike *Bmp4* and *Bmp6*, which have pro-angiogenic effects on cultured ECs, exogenous *Bmp9* is a potent inhibitor of angiogenic responses at concentrations found in the circulation. This suggests that *Bmp9* may play a unique role as a circulating vascular quiescence factor. Interestingly, unlike *Bmp4* (and probably *Bmp6*), *Bmp9* is not inhibited by Noggin, suggesting that selective antagonism by Noggin could determine the net pro-versus anti-angiogenic effects of circulating Bmps in vascular

beds. Despite this, the functional role of circulating Bmp9 (or other Bmp ligands) *in vivo* is unknown. Moreover, recent studies have shown that when used in combination, Bmp9 and TGF- β may act in a cooperative manner to enhance angiogenic responses. These studies emphasize the importance of establishing the functional role of these Bmp-dependent responses in the context of the intact vasculature *in vivo*.

Extracellular Regulators of Bmp Signaling

A number of studies have demonstrated changes in expression of extracellular modulators of Bmp signaling associated with vascular injury and disease. These Bmp regulators have been shown to modify vascular cell function, but there are limited data on their role in regulating vascular structure and/or function *in vivo*. Furthermore, while many of these factors have been shown to modify Bmp signaling, they often have other functional properties, so that changes in their expression are not necessarily associated with alterations in Bmp signaling.

Gremlin

The Bmp antagonist Gremlin promotes aortic VSMC proliferation and migration (141), and is up-regulated in the systemic vasculature of patients with uremia (which is associated with extensive vascular calcification), in a carotid artery injury model and in alveolar hypoxia (associated with the development of PH). However, Gremlin is dynamically regulated and its effects should be interpreted in the context of other components of the Bmp signaling pathway. For example, Gremlin expression in the vascular media is up-regulated in a rat model of vascular calcification, but this is also associated with increased expression of Bmp2. Furthermore, in the carotid artery injury model an early decrease is followed by a prolonged increase in Gremlin expression. These kinetic changes in Gremlin expression correlate inversely with the temporal expression of Bmp4 in another model of carotid artery injury. Similarly, other studies have shown that Bmp4 is co-expressed with Bmp antagonists Noggin, Follistatin, and Matrix Gla protein (MGP) at sites of oscillatory shear stress in the systemic vasculature. These studies support the hypothesis that the primary function of these Bmp antagonists is to provide a temporal limit on Bmp signaling in the context of vascular injury. This underscores the importance of developing integrated approaches to evaluate gene/protein regulation and function in the Bmp signaling pathway in vascular disease.

Bmper/Cv2

Bmper/Cv2 also regulates vascular development. Knockdown of Bmper/Cv2 in embryonic zebrafish results in a defect in vascular patterning. In mammalian cells, Bmper/Cv2 is expressed in ECs from the heart, lung, and skin, and modulates Bmp4-dependent angiogenic responses. Low-level Bmper/Cv2 expression promotes EC sprouting and migration *in vitro*, while higher-level Bmper/Cv2 represses these responses. However, functional evidence that Bmper/Cv2 regulates mammalian vascular homeostasis *in vivo* is lacking.

Matrix Gla-protein

MGP is an extracellular matrix component produced by VSMCs that inhibits or activates Bmp2 and Bmp4 in a

concentration-dependent fashion. MGP-deficient mice have widespread vascular calcification and stenosis of peripheral pulmonary vessels is observed in some patients with Keutel syndrome, which is genetically linked to germ line MGP mutations. There are no data on the effects of these mutations on Bmp signaling. However, over-expression of MGP in the lung (MGP bacterial artificial chromosome transgenic mice) is associated with reduced Bmp-dependent Smad signaling along with reduced pulmonary vascular branching. This suggests that vascular effects of MGP may be mediated through inhibition of Bmp signaling.

Bmp Receptors and Co-Receptors

Definitive evidence that the Bmp receptors play a role in maintaining normal vascular homeostasis and promote vascular disease in humans has come from genetic analyses of patients with rare systemic and pulmonary vascular diseases. Genetic studies of the same receptor mutations in mice phenocopy the corresponding vascular diseases and provide insight into the mechanism by which these receptors regulate embryonic vascular development and homeostasis in the adult. Moreover, there is increasing evidence from these studies that defects in Bmp receptor signaling not only regulate vascular structure but also have potent effects on vascular tone. This section will summarize data on the dominant receptors and co-receptors that have been identified and studied genetically in mice and humans (summarized in Table 3).

Bmpr2

More than 70% of patients with rare, autosomal dominant inherited hereditary pulmonary arterial hypertension (HPAH) inherit mutations at the *BMPR2* locus. In addition, ~20% of patients with apparently idiopathic (nonhereditary) PAH also carry *BMPR2* mutations. These mutations occur throughout the *BMPR2* open reading frame indicating that they are likely to cause loss of function and/or dominant negative effects. Moreover, given that the pathology of HPAH is identical to other forms of PAH, these findings suggest that defects in Bmpr2 signaling may also participate in pathogenesis of other forms of PH not associated with heritable *BMPR2* mutations. This is supported by the observation that components of the Bmp signaling pathway are down-regulated in the lungs of patients with nonhereditary forms of PAH. Despite this, there is no clear consensus as to how Bmpr2 signaling affects the pulmonary vasculature. Moreover, while there is no evidence that HPAH patients are predisposed to develop systemic hypertension or vascular disease, it is completely unknown why *BMPR2* mutations have dominant effects on the pulmonary versus systemic vasculature.

Studies in mice with genetic mutations at the *Bmpr2* locus provide insight into the mechanisms by which *BMPR2* mutations give rise to pulmonary vascular disease in HPAH. Using ribonucleic acid interference (RNAi) in the germline to reduce Bmpr2 expression to ~10% of normal leads to massive intestinal hemorrhage, vascular dysplasia, and impaired VSMC recruitment to pulmonary vessels. This indicates that Bmpr2 plays a role in maintaining normal systemic and pulmonary vascular stability and structure, and is similar to the vascular phenotype seen in mice carrying *Endoglin* and *Alk1* mutations

(see below). Moreover, ~30% of mice with conditional deletion of *Bmpr2* in ECs develop spontaneous PH. This is associated with focal infiltration of inflammatory cells around distal pulmonary arteries, indicating that loss of *Bmpr2* expression in ECs gives rise to local vascular inflammation. Similar effects have been described in another mouse model in which a mutant form of *Bmpr2* is over-expressed in VSMCs. Since these mice also develop spontaneous PH, it is possible that *Bmpr2*-dependent inflammation within the pulmonary vasculature plays a role in the development of PH. This is consistent with the observation that pulmonary vascular lesions in the patients with PAH often contain infiltrating mononuclear cells and lymphocytes. However, the effect of mononuclear cell depletion on the development of PH has yet to be determined. Furthermore, these findings are hard to reconcile with the fact that *Bmp2* and *Bmp4* have pro-inflammatory effects on the systemic vasculature. Since *Bmpr2* is the dominant type 2 receptor required for *Bmp2* and *Bmp4* signaling, this suggests that *Bmpr2* signaling may have opposite, anti- versus pro-inflammatory effects on the pulmonary versus systemic vasculature, respectively. An alternative explanation is that any disturbance in the balance of Bmp signaling (either increased or decreased) enhances pro-inflammatory responses in systemic and pulmonary vasculature. Careful analysis of the systemic vasculature in mice with disruption of *Bmpr2* signaling in ECs would address this question.

Studies in mice carrying heterozygous germ line mutations at the *Bmpr2* locus also provide insight into the pathobiology of HPAH. Heterozygous germ line null and hypomorphic *Bmpr2* mutant mice (*Bmpr2 Δ Ex2*, in which there is an in-frame deletion of Exon 2) do not develop spontaneous PH, but have increased susceptibility to PH in response to inflammatory mediators and serotonin, or chronic hypoxia, respectively. However, none of these models develops alliterative vascular remodeling that is more typical of human HPAH. In fact, if anything, heterozygous null *Bmpr2* mutant mice have reduced pulmonary vascular remodeling in response to hypoxia, suggesting that increased susceptibility to PH does not result from structural alterations in the pulmonary vasculature. It has been argued that this failure to recapitulate the severity of human PAH is a significant limitation of mouse models of PH. However, another possibility is that changes observed in the pulmonary vasculature of mice carrying different *Bmpr2* mutations are indicative of early, pre-clinical events that occur in the pulmonary vasculature of patients with HPAH. For this reason, the observation that heterozygous null and hypomorphic *Bmpr2* mutant mouse pulmonary vasculature show increased pulmonary vasoconstriction in response to different agonists is of particular interest. Moreover, hypomorphic *Bmpr2* mutant mice have a marked defect in EC-dependent pulmonary vasodilatation associated with reduced pulmonary vascular eNOS expression, suggesting that *Bmpr2* mutations may have a dominant effect on EC function. This is consistent with the observation that *Bmpr2* is dominantly expressed in EC versus VSMC compartments of the pulmonary vasculature. Moreover, *Bmp2* (ligand) heterozygous mutant mice which show increased susceptibility to hypoxic PH also have reduced pulmonary vascular eNOS expression and activity. In addition, mice carrying heterozygous germ line mutations at the *Endoglin* locus have

abnormal pulmonary and systemic vascular reactivity and decreased eNOS activity (see below). Taken together, these findings suggest that aberrant Bmp signaling associated with *BMPR2* mutations in patients with HPAH not only regulates vascular cell proliferation, remodeling, and inflammation, but also promotes abnormal pulmonary vascular reactivity in the patients.

Alk1

Inactivating mutations at the *ALK1* locus have been identified in patients with hereditary hemorrhagic telangiectasia type 2 (HHT2). HHT2 is an autosomal dominant heritable disease characterized by vascular dysplasia that results in abnormal, dilated blood vessels and arterio-venous malformations. A functional role for *Alk1* in this disease has been confirmed by gene targeting in mice. Homozygous *Alk1* null mice die embryonically with widespread arteriovenous malformations resulting from defective pericyte recruitment to the primitive vasculature. Similar vascular defects are seen in *Bmpr2*-deficient (germ line RNAi knockdown) and *Endoglin*-null mice, suggesting that all three receptors play a role in inducing or maintaining embryonic vascular stability. Aging adult heterozygous *Alk1* mutant mice also develop systemic vascular malformations that phenocopy the lesions seen in human HHT, and deletion of *Alk1* in ECs alone is sufficient to phenocopy HHT. The same vascular malformations are seen in heterozygous *Endoglin* mutant mice (see below). Furthermore, a subset of patients with HHT2 carrying *ALK1* mutations develop PAH, suggesting that *ALK1* and *BMPR2* mutations have common effects on the pulmonary vasculature. Taken together, these findings suggest that *Alk1* participates with *Bmpr2* and *endoglin* in regulating systemic and pulmonary vascular homeostasis in the adult.

Alk3

ALK3 has not been genetically linked to human disease but has been functionally implicated in vascular biology from genetic studies in mice. *Alk3* is ubiquitously expressed during development and homozygous deletion in mice results in embryonic lethality due to gastrulation defects. However, conditional *Alk3* deletion in embryonic vascular progenitor cells results in widespread vascular abnormalities in vessel maturation and remodeling. Moreover, patchy conditional deletion of *Alk3* in VSMCs reduced the ability of pulmonary VSMCs to remodel in response to chronic hypoxia. These findings suggest that *Alk3* expression in VSMCs regulates Bmp-dependent vascular remodeling. Stabilization of systemic and pulmonary vasculature may be mediated by *Alk3*-dependent repression of VEGF. Furthermore, since *Bmp4*-deficient mice have defective pulmonary vascular remodeling and VSMC proliferation in response to chronic hypoxia, these findings also suggest that *Bmp4* may be signaling through *Alk3* in the lung vasculature to promote VSMC proliferation and vascular remodeling.

Endoglin

Genetic studies show that patients with HHT1 inherit heterozygous mutations at the *ENDOGLIN* (*ENG*) locus. Moreover, there are case reports of families with HHT1 and PAH that have *ENG* mutations, suggesting that *endoglin* may play a common role in regulating both systemic and pulmonary vascular

homeostasis. The vascular defects in patients with HHT1 are indistinguishable from those seen in patients with HHT2 who inherited heterozygous mutations at the *Alk1* locus. Heterozygous *Eng* mutant mice phenocopy HHT. Recent studies have also shown that these mice also develop spontaneous PH. These findings provide further evidence that *Alk1*, endoglin, and *Bmpr2* play a cooperative role in regulating both systemic and pulmonary vascular homeostasis. There is evidence that *Eng* heterozygous mutant mice also have abnormalities in systemic and pulmonary vascular tone, and that these effects are mediated by ROS-dependent uncoupling of eNOS in ECs. Moreover, the finding that heterozygous null *Bmpr2*, and *Bmpr2* hypomorphic mutant mice also have abnormalities in pulmonary vascular tone associated with decreased activity and/or expression of eNOS, suggests that endoglin-dependent regulation of eNOS may be mediated through a *Bmpr2*-dependent pathway. These findings provide further support for the hypothesis that Bmp signaling not only regulates structural changes in the systemic and pulmonary vasculature, but also plays an important role in maintaining normal vascular tone.

Defects in endoglin signaling are also reported in patients with pregnancy-associated hypertension resulting from pre-eclampsia (a condition resulting from destabilization and leakage of maternal vascular ECs). Soluble endoglin is detected in the sera of women with pre-eclampsia. Moreover, increased levels of placental derived soluble endoglin and soluble vascular endothelial growth factor receptor 1 (Vegfr1) correlate with severity of pre-eclampsia, and adenoviral over-expression studies indicate that soluble endoglin and soluble Vegfr1 act in a cooperative manner to induce severe pre-eclampsia in pregnant rats. The mechanism by which soluble endoglin mediates these effects is unknown, but could result from scavenging Bmp9, which may act as a circulating endothelial quiescence factor. In addition to the association with pre-eclampsia, endoglin may also play a role in the development of aging associated hypertension. Two splice variants of endoglin have been described, long (L-) and short (S-) endoglin, which differ in their intracellular tails. The ratio of S/L endoglin increases with aging in mice, while transgenic over-expression of S-endoglin in ECs leads to systemic hypertension associated with decreased eNOS activity. Since L-endoglin promotes *Alk1* and S-endoglin promotes *Alk5* signaling in ECs, alterations in the ratio of the two isoforms may modify vascular function by influencing the balance of *Alk1/5* signaling in ECs.

Downstream Signaling

Bmp signaling activates both Smad-dependent and Smad-independent responses in a variety of cultured vascular cell types. While the functional roles of some of these responses have been defined by genetic studies in mice, many of these effects are poorly defined and their roles in mediating Bmp-dependent effects in vascular development and disease are largely unknown.

Bmp-activated Smads

Biochemical studies tend to lump together Bmp-activated Smad1, Smad5, and Smad8 as a single response. However, genetic studies indicate that different Smads have nonredundant functions at different stages of embryonic development.

Germ line *Smad5*-null mice die early in gestation with defects in vascular organization and pericyte recruitment to the primitive extra-embryonic (yolk sac) and embryonic vasculature. These defects are reminiscent of the angiogenesis defects seen in *Bmpr2* knockdown and *Eng* and *Alk1*-null embryos, suggesting Smad5 may be functioning in the same pathway. However, mice in which Smad5 is conditionally deleted in ECs slightly later in development are viable and do not have defects in the embryonic or adult vasculature, indicating that there is functional compensation for loss of Smad5 expression later in development. In contrast to the *Smad5*-null mouse, germ line *Smad1*-null mutants have prominent defects in chorioallantoic membrane fusion, but only minor defects (possible secondary) in the yolk sack vasculature. Moreover, *Smad8* mutant mice are viable, indicating that Smad1 and Smad8 play redundant roles in early and late embryonic vascular development, respectively. Interestingly, aging *Smad8*-null mice develop spontaneous remodeling of the intrapulmonary vasculature reminiscent of the obliterative pulmonary vasculopathy seen in patients with HPAH. Furthermore, Smad8 is highly expressed in the pulmonary vasculature, and an inactivating, nonsense mutation in *SMAD8* has recently been reported in one idiopathic PAH patient. Together, these findings indicate that Smad8 plays a selective role in regulating adult pulmonary vascular homeostasis, and suggest that defective Smad8 signaling could mediate *Bmpr2*-dependent effects in HPAH.

Smad4

In humans, *SMAD4* mutations have been linked to patients with combined HHT and juvenile polyposis (JV/HHT). Moreover, while *Smad4*-deficient mice display early embryonic lethality due to defective gastrulation, conditional deletion of *Smad4* in ECs leads to defects in the extra-embryonic and embryonic vasculature that resemble those seen in *Alk1* and *Eng* knockout mice. Taken together, these findings suggest that Bmp-dependent Smad5/4 signaling mediates early angiogenesis in the developing embryo. Genetic linkage to HHT suggests that Smad4 also regulates vascular homeostasis in adults. However, Smad4 is a common mediator of Bmp and TGF- β activated Smad signaling, so the relative contribution of Smad4 in mediating Bmp-dependent effects in the vasculature is unknown.

Smad6

Smad6 is widely expressed in the cardiovascular system in the embryo, and in the adult Smad6 expression is largely restricted to the vascular ECs. While a significant proportion of *Smad6* mutant mice die due to cardiac septation defects, those that survive develop systemic hypertension, enhanced vascular contractility, and impaired NO-dependent vasodilatation of aortic rings. These findings are reminiscent of the effects of exogenous Bmp2 and Bmp4 on the systemic vasculature, but are difficult to reconcile with the known functional properties of Smad6 as a selective inhibitor of Bmp-dependent Smad signaling. This is consistent with the observation that these Bmp2- and Bmp4-dependent effects are mediated through Smad-independent ROS-mediated mechanisms, and that the effects of Smad6 on the systemic vasculature may be independent of its effects on Bmp-activated Smad signaling.

Smad-independent signaling

Bmp ligands activate a range of different Smad-independent transcriptional and nontranscriptional pathways in cultured vascular cells. However, the functional role of these responses in mediating Bmp-dependent effects in the intact vasculature is largely unknown. An exception to this is the downstream mediator of Bmp-dependent MAPK signaling, Tak1. *Tak1*-deficient mice have abnormal extra-embryonic and embryonic vasculature resulting from defective VSMC recruitment to the remodeling vessels. This phenotype is identical to the *Alk1* and *Eng*-null mice, suggesting that Tak1 is mediating signaling downstream of the Alk1/Eng signaling complex. Moreover, over-expression of Tak1 rescues the vascular phenotype resulting from *Alk1* deficiency in zebrafish embryos. However, it is unclear whether these effects result from Tak1-dependent activation of p38 MAPK and JNK, or result from the effects of Tak1-dependent activation of Bmp activated Smads. This illustrates the complexity of understanding the true nature of Bmp signaling in the intact organism, and the challenges ahead.

Concluding Remarks

The functional roles of Bmp signaling defects in human vascular diseases remain unclear. However, genetic studies in mice indicate that different components of the Bmp signaling pathway stabilize EC/VSMC interactions in the developing vasculature, suggesting that this pathway may also be required to maintain vascular stability in the adult. Functional studies in adult mice also indicate that Bmp signaling plays a role in regulating vascular reactivity, EC function, and inflammation. New discoveries are revealing novel roles for Bmp signaling,

such as regulating microRNAs. Additionally, given that expression of Bmp ligands is often controlled by long-range regulatory elements, dysfunctional signaling may be involved in human disease not attributable to mutation at the gene locus. Moreover, with the identification of small-molecule inhibitors (and potentially activators) of Bmp signaling using high content screening, new possibilities for modulation *in vivo* will assist in future discovery and therapeutics.

Glossary

Angiotensin Peptide produced by the action of the enzyme renin on the protein angiotensinogen.

G protein Trimeric complex of α , β , and γ subunits. Activation of a G-protein-coupled receptor results in dissociation of the G α subunit, which in turn activates signaling proteins such as adenylyl cyclase, certain ion channels, and phospholipases. The activity of the G α subunit is terminated by endogenous GTPase activity, followed by reassociation of the G α with G $\beta\gamma$ subunit.

Ischemia Loss of blood flow with resultant metabolic insufficiency of a tissue bed.

Myocardial infarction Death of heart muscle following prolonged, complete ischemia.

Prostaglandin Autocoid (local hormone) produced by the action of cyclooxygenase 1 or cyclooxygenase 2 on arachidonic acid. A variety of prostaglandins may be produced, each with specific biological actions elicited by binding to cell-surface receptors.

Single nucleotide polymorphism Difference at a specific place in a DNA sequence of a single nucleotide. The two gene variants are alleles.

Overview

Most G-protein agonists are hormones or neurotransmitters synthesized intracellularly and stored in secretory granules prior to release. By contrast, bradykinin is a member of the kallikrein-kininogen-kinin system, a complex of two substrates (kininogens) activated by two enzymes (kallikreins) to produce four inflammatory mediators (kinins) that bind to two bradykinin receptors (Figure 1).

The substrates, high-molecular-weight (HMW) kininogen and low-molecular-weight (LMW) kininogen, are α_2 macroglobulins produced by alternative splicing of the same mRNA. HMW kininogen circulates in blood in a 1:1 complex with plasma prekallikrein. Upon tissue injury, factor XII, a component of the coagulation cascade, cleaves plasma prekallikrein to activate it. Plasma kallikrein acts on HMW kininogen to release bradykinin (plasma kallikrein also activates LMW kininogen to produce bradykinin). Tissue kallikrein is synthesized by many types of epithelial cells and secretory cells. Thus, unlike plasma kallikrein, it acts locally. Tissue kallikrein acts only on LMW kininogen and cleaves it one residue to the amino terminus of the site of cleavage of plasma kallikrein to produce a decapeptide, kallidin (or Lys-bradykinin). Bradykinin and kallidin are equipotent agonists of bradykinin B2 receptors and are usually referred to generically as bradykinin or kinins. It should be noted that bradykinin and kallidin are chemically heterogeneous since the proline residues within the peptides may be partially hydroxylated.

Kinins are metabolized further by a variety of enzymes, most of which inactivate them. The major inactivating enzyme is kininase II, especially prevalent in the lungs and in vascular beds, and its activity is largely responsible for the very short half-life of the kinins, about 15 s. Kininase II removes the carboxyterminal dipeptide from both bradykinin and kallidin. Kininase II is also known as an angiotensin-converting enzyme because it converts angiotensin I into the vasoconstrictor angiotensin II. Of importance to the present discussion, another enzyme, kininase I, removes the carboxyterminal Arg from bradykinin and kallidin to produce

the other two inflammatory mediators, the bradykinin B1 receptor agonists desArg⁹-bradykinin and desArg¹⁰-kallidin, respectively. Like the agonists of B2 receptors, bradykinin and kallidin, the desArg metabolites have similar potency as agonists of B1 receptors.

Nearly all tissues express B2 receptors, and bradykinin-induced activation of B2 receptors is implicated in many disease states. B1 receptors are expressed in only a few tissues under normal conditions and only in very small numbers. Several disease states are associated with rapid induction of B1 receptors in specific tissues.

B1 Receptor

The existence of a B1 receptor activated by what had been considered an inactive bradykinin metabolite, des-Arg⁹-bradykinin, was a provocative proposal. This receptor was not found in normal tissues, but was found to be induced during incubation of tissues *in vitro*. Identification of a synthetic B1 receptor antagonist, desArg⁹-Leu⁸-bradykinin, added credence to the existence of a physiologic receptor. Later, induction of B1 receptors was found pharmacologically to be associated with specific disease processes *in vivo*, and in 1994, the existence of the B1 receptor was conclusively confirmed with the cloning of the receptor protein.

B1 receptors have been implicated in hyperalgesia, plasma extravasation, white blood cell activation, and accumulation, and in the control of blood pressure. However, it seems certain that complete understanding of the roles of this inducible receptor in pathophysiology is not at hand. B1 receptors from several species have been cloned. They are typical G-protein-coupled receptors in sequence. The human receptor has a predicted sequence of 353 amino acids and is only 36% homologous to B2 receptors. The B1 receptor activates phosphatidylinositol-specific phospholipase C and possibly phospholipase A₂.

The B1 receptor gene is composed of three exons. The entire coding region for the receptor is contained within the third

Figure 1 Formation of endogenous bradykinin receptor ligands. Bradykinin and kallidin bind to B2 receptors, whereas desArg⁹-bradykinin and desArg¹⁰-kallidin bind to B1 receptors. Both bradykinin and kallidin may contain some proline residues that are hydroxylated. If hydroxylated, the most common residue is Pro³ in bradykinin and Pro⁴ in kallidin (shown hydroxylated in the figure).

exon. A variety of polymorphisms have been identified. One, a G/C single-nucleotide polymorphism in the promoter region has been associated with disease. Expression of the C allele is higher than the G allele, and patients with the G allele have greater incidence of inflammatory bowel disease and end-stage renal disease.

B1 Receptor Regulation

Most G-protein-coupled receptors are internalized quickly after the binding of their ligands. B1 receptors, however, are not internalized following binding of desArg-kinins. This results in very prolonged activation of signal transduction, which translates into rather few receptors per cell being necessary for biological activity when compared to many other G-protein-coupled receptors. Ligand-binding studies in a variety of tissues reveal only hundreds to a few thousand B1 receptors per cell, whereas most G-protein-coupled receptors, including B2 receptors, are found in tens of thousands per cell.

In contrast to prolonged phosphatidylinositol turnover, B1 receptor-mediated arachidonic acid release and prostaglandin synthesis are short-lived, which is similar to B2 receptors. The mechanism for this differential desensitization is unknown, but it may be linked to sequestered pools of arachidonate-containing phospholipids or phosphorylation of an intracellular binding site for a transduction protein.

B1 receptors have been shown by immunoprecipitation studies to couple to G_{zq} and G_{zi}. These G-proteins commonly couple receptors to phosphatidylinositol-specific phospholipase C and elevation of intracellular free calcium activity. Activation of B1 receptors leads to the elevation of intracellular free calcium activity by increasing calcium entry into the cell; this is in contrast to the B2 receptor, which acts primarily to release bound intracellular calcium.

Regulation of B1 Receptor Induction

Unlike many G-protein-coupled receptors, the primary regulation of the B1 receptor number appears to occur by

transcriptional induction. Biological studies have found that B1 receptor expression is induced by a variety of cytokines including endotoxin, interleukin 1 β , and tumor necrosis factor. The specific domains affected by these stimulating ligands have not been identified, but activation of B1 receptor transcription has been correlated to the activation of the transcription factor nuclear factor-kappa B (NF- κ B).

The regulation of the B1 receptor gene has also been shown to be regulated by stabilization of mRNA. Interleukin 1 treatment of cells has been demonstrated to double the half-life of B1 receptor mRNA. In addition, protein synthesis inhibitors increase B1 receptor gene stability, suggesting the existence of a short-lived protein that causes destabilization. This protein may interact with the 3' untranslated region, since experimentally altering the 3' untranslated region results in B1 receptor messenger RNAs (mRNAs) with varying half-lives.

B1 Receptor Knockout Animals

B1 receptor knockout mice have been reported to develop normally and to have normal blood pressure. By contrast, when inflammatory stimuli are applied, dramatic reductions in accumulation and apoptosis of neutrophils have been reported, as well as hypoalgesia; this is consistent with pharmacological evidence presented in the past.

B2 Receptors

B2 receptors mediate bronchoconstriction, local blood flow regulation, hypotension, acute inflammatory reactions, pain, and hyperalgesia. B2 receptors from several species have been cloned. Like B1 receptors, they are typical G-protein-coupled receptors in sequence. The human receptor has a predicted sequence of 364 amino acids. Both B1 and B2 receptors are found on chromosome 14 in humans, only about 12 kb apart. Like B1 receptors, B2 receptors activate phosphatidylinositol-specific phospholipase C. In addition, in most tissues, B2 receptor activation results in the production of prostaglandins and other arachidonic acid metabolites.

The B2 receptor gene is composed of three exons, of which exon 2 and exon 3 provide the coding region for the receptor. Bradykinin has been implicated in hypertension for decades. More than 80 single-nucleotide polymorphisms have been identified for the B2 receptor. The promoter region for the B2 receptor contains a single-nucleotide polymorphism, T/C. The C allele has been demonstrated to be an independent risk factor for essential hypertension in several ethnic groups. Several other alleles have been reported and were found to be differentially associated with several disease states. Expansion of these observations promises the potential to define the role of bradykinin in a variety of physiologic and pathophysiologic states.

B2 Receptor Regulation

In contrast to the B1 receptor, B2 receptor number does not seem to be significantly regulated by inducible gene expression. Instead, B2 receptors are constitutively expressed, as is the case for many G-protein-coupled receptors. Activation of the B2 receptor by binding of bradykinin results in rapid internalization of the receptor protein by endocytosis, occurring within a few minutes. Internalization results in cessation of the biological activity of the receptor. Thus, activation of a particular B2 receptor results in a transient increase in intracellular calcium activity and transient prostaglandin release. Receptors are recycled intracellularly, with stripping of bradykinin and the return of a reactivated B2 receptor to the cell surface where it may be reactivated. Most G-protein-coupled receptors are internalized following attachment to arrestin and dynamin-dependent clathrin-coated vesicles. By contrast, the B2 receptor becomes associated with caveolae.

B2 Signal Transduction

B2 receptors have been demonstrated to activate all of the signal transduction mechanisms described for G-protein-coupled receptors (Figure 2).

Any given cell type supports only a few of the transduction pathways, and these are primarily controlled by the specific G proteins expressed by the given cell type. B2 receptors have been shown by immunoprecipitation studies to couple to $G_{\alpha q}$, which mediates interaction with phosphatidylinositol-specific phospholipase C. B2 receptors have also been shown by immunoprecipitation to couple to $G_{\alpha i}$. G-protein depletion studies have suggested that $G_{\alpha i}(2)$ and $G_{\alpha i}(3)$ couple B2 receptors to arachidonic acid release, presumably through the activation of phospholipase A_2 . In contrast to B1 receptors, activation of B2 receptors results in increased intracellular calcium activity from the release of calcium from intracellular stores.

B2 Receptor Knockout Animals

Studies with B2 receptor knockout mice have shown that the animals develop normally. However, one study found that when animals are fed a high-salt diet, severe hypertension occurs. It has also been reported that the renin-angiotensin system was abnormal (the kallikrein-kinin system and the renin-angiotensin system are antagonistic hemodynamic regulatory systems that play important roles in blood pressure

Figure 2 Signal transduction elicited by B2 receptors: BK, bradykinin or kallidin; PLA₂, phospholipase A₂; IP₃, inositol trisphosphate; DAG, diacylglycerol; PG, prostaglandin; LT, leukotriene. Not shown is phospholipase D, which, in some cells, provides a shuttle for arachidonic acid to appropriate substrates for hormone-sensitive phospholipase A₂. In most cells, bradykinin does not directly alter cAMP concentration; often, this occurs as a consequence of PGE₂ binding to its receptor.

homeostasis) and abnormal renal development occurred. A variety of cardiac defects have also been reported as well as chronically elevated heart rate.

Other Bradykinin Receptors

Many pharmacologic studies using bradykinin analogs have yielded data suggestive of additional bradykinin receptors, or at least heterogeneity of bradykinin receptors. For example, in smooth muscle preparations, there is evidence for expression of different B2-like receptors expressed by the smooth muscle and the neuronal endings in the smooth muscle. Similarly, B3 receptors have been reported in trachea, and B4 and B5 receptors have been reported in opossum esophagus. A criticism of all of these studies is the use of rather weak bradykinin analogs, with dissociation constants of several nanomolars, compared to pM dissociation constant for bradykinin itself. No genetic evidence for additional receptors beyond B1 and B2 has been obtained to date.

Bradykinin Receptor Antagonists in Clinical Medicine

While highly potent peptide antagonists for B1 receptors have been described, none to date have been evaluated in clinical trials. By contrast, several peptide antagonists for B2 receptors have been evaluated as anti-inflammatory agents, including NPC 567 and Hoe 140. In addition, several nonpeptide antagonists of B2 receptors have been described. Hoe 140 (icatibant) was approved in Europe 2009 for the treatment of hereditary angioedema. Icatibant has also been found to reduce airways hyperresponsiveness and eosinophilia following antigen challenge in patients allergic to grass pollen antigen. CP-1027 (Bradycor) has been found to reduce intracranial pressure following traumatic brain injury.

An issue that has slowed clinical development of such antagonists is the observation that bradykinin appears to play an important role in coronary artery function. It has been suggested that chronic antagonism of B2 receptors in patients with coronary artery disease may have deleterious effects during ischemic events, perhaps even triggering myocardial infarction.

Branched-Chain Amino Acids

D T Chuang, University of Texas Southwestern Medical Center, Dallas, TX, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Activity state The ratio of the actual (partially de-phosphorylated) activity to the maximal (fully de-phosphorylated) activity of the mammalian mitochondrial branched-chain α -ketoacid complex (BCKDC). The activity state represents the percentage of the total BCKDC that is active in a tissue under defined physiological conditions.

Ketoacidosis A clinical condition associated with the accumulation of the BCKDs derived from branched-chain amino acids (BCAAs) leucine, isoleucine, and valine present in dietary proteins. This pathological state is presented by patients with the maple syrup urine disease caused by congenital defects in the BCKDC.

Metabolon The association of several related metabolic enzymes to form a supramolecular structure. The advantage of such a supramolecular assembly is to channel substrates between two juxtaposed steps in a metabolic pathway for maximal efficiency in an appropriate intracellular location.

Oxidative decarboxylation The removal of a CO₂ group from a molecule by a decarboxylase/dehydrogenase with a concomitant transfer of electrons from the substrate to a biological electron acceptor. For the branched-chain α -ketoacids (BCKDs), this reaction is catalyzed by the BCKDC coupled with the reduction of nicotinamide adenine dinucleotide (NAD⁺).

Phosphorylation The posttranslational modification of a protein or enzyme molecule by a specific kinase, in which the γ -phosphoryl group from ATP is incorporated into a serine, threonine, or tyrosine residue of the protein/enzyme as a means to regulate its biological activity.

Transamination A reversible enzymatic reaction that converts an amino acid into a corresponding α -ketoacid. For BCAAs, this reaction is carried out by the distinct isozymes of branched-chain aminotransferase both in the cytoplasm and in the mitochondrion.

The branched-chain α -ketoacids (BCKAs) comprise α -ketoisocaproate (KIC), α -keto- β -methylisovalerate (KMV), and α -ketoisovalerate (KIV) derived from branched-chain amino acids (BCAAs) leucine, isoleucine, and valine, respectively, through reversible transamination. The oxidative decarboxylation of these three BCKAs is catalyzed by a single branched-chain α -ketoacid dehydrogenase complex (BCKDC) giving rise to the corresponding branched-chain acyl-coenzymes (acyl-CoAs) (reaction [1]):

In patients with heritable maple syrup urine disease (MSUD), activity of the BCKDC is deficient. This metabolic block results in the accumulation of BCAAs and BCKAs. Clinical manifestations include neonatal or late onset of often-fatal ketoacidosis, encephalopathy, and other acute and chronic neurological dysfunction, as well as mental retardation in survivors. A distinct phenotype is the strong maple syrup odor in the urine of patients, and hence the name of this metabolic disease. There are currently five clinical phenotypes associated with MSUD: classic, intermediate, intermittent, thiamin-responsive, and E3-deficient. The prevalence of MSUD is one in 185 000 live births worldwide.

Degradative Pathways of BCAAs

The oxidation of BCAAs leucine, isoleucine, and valine begins with the transport of these amino acids into cells through the Na⁺-independent L transporter on the plasma membrane. In the cell, the BCAAs undergo the first transamination step

catalyzed by BCAA aminotransferases (BCATs), which are in either the cytosolic or mitochondrial compartment, to produce BCKAs (Figure 1). The second step, that is, the oxidative decarboxylation of BCKAs catalyzed by the mammalian BCKDC, occurs exclusively in the mitochondrion. The reaction products of KIC, KMV, and KIV are isovaleryl-CoA, α -methylbutyryl-CoA, and isobutyryl-CoA, respectively. These branched-chain acyl-CoAs subsequently undergo the third step, that is, dehydrogenation by specific acyl-CoA dehydrogenases. The dehydrogenation of isovaleryl-CoA is catalyzed by isovaleryl-CoA dehydrogenase, and the dehydrogenation of α -methylbutyryl-CoA and isobutyryl-CoA is carried out by α -methyl branched-chain acyl-CoA dehydrogenase. After these three steps, the degradative pathways for each of BCKAs diverge. Leucine yields acetyl-CoA and acetoacetate as end products, and is therefore a ketogenic amino acid. Valine produces succinyl-CoA, and is accordingly glucogenic. Succinyl-CoA enters the Krebs cycle, and is eventually converted to glucose through gluconeogenesis. Isoleucine is both ketogenic and glucogenic since it is metabolized to acetyl-CoA and succinyl-CoA.

Interorgan Relationships

Oxidation of BCAAs involves extensive interplay of metabolites between muscle and liver in the rat. This is due to the nonuniform distribution of BCATs and the BCKDC between organs and tissues. In rat skeletal muscle, BCAT activity is high, but BCKDC activity is low. A reverse situation exists in rat liver with respect to levels of the two enzyme activities. Both rat liver and kidney degrade BCKAs at high rates, but in hepatectomized rats

Figure 1 Catabolic pathways for the branched-chain amino acids (BCAAs) leucine, isoleucine, and valine. The first three common reactions are catalyzed by the following enzymes: reversible transamination by BCAA aminotransferases (BCATs) (1), oxidative decarboxylation of BCKAs and esterification of CoASH by the single mitochondrial branched-chain α -ketoacid dehydrogenase (BCKD) complex (2), and dehydrogenation by isovaleryl-CoA dehydrogenase or α -methyl branched-chain acyl-CoA dehydrogenase. After these steps, the degradation pathway for each amino acid diverges. As end products, leucine yields acetyl-CoA and acetoacetic acid; isoleucine produces acetyl-CoA and succinyl-CoA; and valine is converted exclusively to succinyl-CoA. The solid horizontal bar (center) depicts the metabolic block imposed by maple syrup urine disease (MSUD) mutations in the BCKDC.

leucine oxidation is decreased. This led to the prevailing view, based on the rat model, that the primary role of muscle is transamination of BCAAs, which provides the major source of circulating BCKAs. These are then transported to liver, kidney, and heart, where they are oxidized. However, the interorgan shuttling of BCAA metabolites may not occur in humans. Studies have shown that BCKDC activity in the human liver is similar to that in skeletal muscle, but the human liver exhibits twice as high BCAT activity as human skeletal muscle. This finding suggests that human liver is capable of oxidizing BCAAs *in situ* and does not depend on BCAT activity in skeletal muscle for the conversion of BCAAs to BCKAs. As skeletal muscle comprises 40% of the body mass, this tissue is likely the major site for BCAA oxidation in humans.

Regulation of BCAA and BCKA Oxidation

The oxidation of BCAAs and BCKAs is tightly regulated and exhibits tissue-specific patterns. The plasma concentrations of BCAAs and BCKAs are elevated in starvation and in clinical conditions such as diabetes mellitus, obesity, and MSUD. Paradoxically, BCAA oxidation is accelerated in muscles from fasted and diabetic rats. Epinephrine (10^{-5} – 10^{-6} M) and glucagon (2×10^{-8} to 5×10^{-9} M) were shown to also stimulate BCAA oxidation in the heart and hemidiaphragms of rats. Insulin decreases the oxidation of BCKAs in striated muscle of fed rats, whereas the same hormone increases oxidative decarboxylation of the ketoacids during starvation. Clofibrate administration augments BCAA oxidation in muscle, but inhibits their

degradation in liver. Carnitine, ketone bodies, hexanoate, and octanoate increase the oxidation of leucine by skeletal muscle, whereas pyruvate and decanoate exert inhibitory effects. The metabolism of KIC in isolated rat hepatocytes is inhibited by fatty acids, KIV, KMV, and pyruvate. It is now known that the regulation of BCAA and BCKA oxidation is largely mediated through the reversible phosphorylation of the BCKDC (see the section Dietary and Hormonal Regulation of the BCKDC).

Leucine as a Nutrition and Endocrine Signal

Among BCAAs, leucine is recognized as a nutrition signal that promotes protein synthesis via the activation of the mammalian target of rapamycin (mTOR) complex 1 and its downstream targets. KIC derived from leucine, on the other hand, inhibits protein degradation. Based on these properties, BCAA supplementation has been clinically used for the treatment of liver disease, sepsis, and burns. Moreover, leucine or BCAA supplements in diets reduce body fat mass and body weight and augment glucose oxidation in rodents. These findings suggest that leucine supplements may be beneficial to controlling obesity and type 2 diabetes. The significance of leucine signaling was demonstrated in a mitochondrial BCAT (BCATm) knockout model. The BCATm^{-/-} mice showed elevated plasma BCAA levels and significantly reduced fat and body mass. The energy expenditure in the animal model is markedly increased with improved glucose and insulin tolerance despite increased food intake. The increased energy expenditure and the resulting weight loss are explained by a futile cycle depicted in Figure 2. The cycle is implemented by increased protein synthesis promoted by leucine, which is coupled with the opposing accelerated proteolysis resulting from the relief of KIC-mediated inhibition. These findings strongly suggest that leucine signaling plays an important role in reducing fat and body mass through increased energy expenditure and insulin sensitivity.

In pancreatic islet β -cells, leucine is a known insulin secretagogue that acutely stimulates insulin secretion. Long-term treatment with leucine improves impaired insulin secretion from the islet cells of diabetic patients with a better glycemic control. Leucine pool in the islet serves as both an energy source and an allosteric activator of glutamate dehydrogenase (GDH), which results in increased glutaminolysis. Leucine-mediated glutaminolysis is shown to be critical for interprandial insulin release when blood glucose levels are low.

The Macromolecular Organization of the BCKDC

The mammalian BCKDC is a member of the highly conserved α -ketoacid dehydrogenase complexes with similar structure and function, comprising pyruvate dehydrogenase complex (PDC), α -ketoglutarate dehydrogenase complex (α -KGDC), and the BCKDC. The mammalian BCKD multienzyme complex contains three catalytic components: a heterotetrameric ($\alpha_2\beta_2$) BCKA decarboxylase or E1, a homo-24 meric dihydrolipoyl transacylase or E2, and a homodimeric dihydrolipoamide dehydrogenase or E3. The E1 and E2 components are specific for the BCKDC, whereas the E3 component is common

Figure 2 An energy-wasting futile cycle in mitochondrial BCAT (BCATm) knockout mice. The deletion of BCATm results in an increased leucine level, which promotes protein synthesis through the mTOR kinase-mediated signaling pathway. Reciprocally, the reduced pool size of α -ketoisocaproate (α -KIC) in BCATm-deficient mice removes the inhibition of protein degradation by α -KIC, leading to accelerated proteolysis. The increased protein synthesis accompanied by an accelerated protein degradation results in an energy-wasting futile cycle. The increased circulating leucine concentration also enhances insulin sensitivity associated with reduced body fat resulting from increased energy expenditure. Reproduced from Fried SK and Watford M (2007) Leucine weight with a futile cycle. *Cell Metabolism* 6: 155–156, with permission from Elsevier.

among the three α -ketoacid dehydrogenase complexes. In addition, the mammalian BCKDC contains two regulatory enzymes: the specific kinase and the specific phosphatase that regulate activity of the BCKDC through the phosphorylation (inactivation)/dephosphorylation (activation) cycle. The six subunits with their cofactors and prosthetic groups that make up the mammalian BCKDC are shown in Table 1. Except the phosphatase, three-dimensional structures for E1, E3, and the three E2 domains including the 24-meric cubic core of the mammalian BCKDC have been determined. The BCKDC is organized around the cubic E2 core, to which 12 copies of E1, up to six copies of E3, and unknown numbers of the kinase and the phosphatase are attached through ionic interactions (Figure 3). The molecular mass of the BCKD multienzyme complex is estimated to be 4×10^6 Da. The purified bovine E1–E2 subcomplex has a sedimentation coefficient ($S_{20,w}$) of 40 S. The E3 component has low affinity for the E2 core, and was mostly lost during purification of the mammalian BCKDC.

The reaction steps catalyzed by the three enzyme components are also shown in Figure 3. The E1 component catalyzes a thiamin diphosphate (ThDP)-mediated decarboxylation of the α -ketoacids and the subsequent reduction of the lipoyl moiety covalently bound to E2. The reduced lipoyl moiety and the lipoyl domain serve as a swinging arm to transfer the acyl group from E1 to CoA giving rise to acyl-CoA. Finally, the E3-component with tightly bound flavin adenine dinucleotide (FAD) reoxidizes the dihydrolipoyl residue of E2 with NAD^+ as the ultimate electron acceptor. The net or overall reaction is the production of a branched-chain acyl-CoA, CO_2 , and

Table 1 Component enzymes and subunit composition of the mammalian branched-chain α -ketoacid dehydrogenase complex

Component	Molecular mass (Da)	Prosthetic group (P) and cofactor (C)
BCKA decarboxylase (E1)	1.7×10^5 ($\alpha_2 \beta_2$)	ThDP (C)
α -Subunit	46 500	Mg ²⁺ (C)
β -Subunit	37 200	K ⁺
Dihydrolipoyl transacylase (E2)	1.1×10^6 (α_{24})	Lipoic acid (P)

NADH from a α -ketoacid, CoA, and NAD⁺ (Figure 3 and reaction [1]).

Dietary and Hormonal Regulation of the BCKDC

The regulation of BCKA oxidation was shown to be at the BCKDC step by using inhibitors such as oleate and palmitoyl carnitine. The mammalian BCKDC is negatively regulated by the reversible phosphorylation of the Ser-292 and Ser-302 residues in the E1 α subunit. The activity state of the BCKDC in different tissues is the ratio of the actual activity of a partially de-phosphorylated form to the maximal activity of the fully de-phosphorylated form. Thus, the activity state represents the percentage of the total BCKDC that is active in a given tissue or cell type. Studies showed that the activity state of the BCKDC in human tissues is 40% in heart, 26% in skeletal muscle, 28% in liver, and only 14% in kidney. Rats fed with low-protein diets show a reduction in the activity state, but not the amount, of the BCKDC in hepatocytes, compared to chow-fed rats. The decrease in activity state inversely correlates with an increase in the amounts of the BCKD kinase protein and mRNA in rat liver. Starvation, exercise, and diabetes stimulate the activity of the BCKDC in skeletal muscle by increasing the

Figure 3 Model for structural organization and individual component reactions of the branched-chain α -ketoacid complex (BCKDC). The macromolecular structure (4×10^6 Da in size) is organized about a cubic transacylase (E2) core (based on the structure of *Azotobacter* pyruvate dehydrogenase E2), to which a decarboxylase (E1) (based upon *Pseudomonas* branched-chain α -ketoacid (BCKD) E1 structure) and a dehydrogenase (E3) (according to the structure of *Azotobacter* pyruvate dehydrogenase E3) are attached through ionic interactions. E2 of the BCKDC contains 24 identical subunits with each polypeptide made up of three folded domains – lipoyl (LD), E1/E3-binding (BD), and the E2 core domains – that are linked by flexible regions (represented by dotted lines). E1 $\alpha_2\beta_2$ heterotetramers or E3 homodimers are attached to BD. The BCKD kinase and BCKD phosphatase (not shown) bind to LD. E1 catalyzes the thiamin diphosphate (ThDP)-mediated oxidative decarboxylation of α -ketoacids. The ThDP-hydroxyacyl moiety is transferred to a reduced lipoyl prosthetic group (in the box) on LD. The flexible LD carries S-acyldihydrolipoamide to the active site in the E2 core to generate acyl-CoA. The reduced lipoyl moiety on LD is oxidized by E3 on BD with the concomitant reduction of nicotinamide adenine dinucleotide (NAD⁺). The sum of the above component reactions is the oxidative decarboxylation of BCKAs (reaction [1] in the text). Reproduced from Aevarsson A, Seger K, Turley S, Sokatch JR, and Hol WG (1999) Crystal structure of 2-oxoisovalerate dehydrogenase and the architecture of 2-oxo acid dehydrogenase multienzyme complexes. *Nature Structural Biology* 6: 785–792, with permission from Nature.

proportion of active or de-phosphorylated enzyme. The activation of BCKDC in exercise is caused by the dissociation of BCKD kinase from the BCKDC, which results in the inactivation of BCKD kinase. Glucocorticoids and acidification also significantly increase the activity state of the BCKDC in pig kidney cells expressing the hormone receptor. Glucocorticoids causes a marked reduction in the BCKD kinase mRNA level in rat hepatoma cells and rat liver, which explains the increased activity state of BCKDC.

The pivotal role of reversible phosphorylation in downregulating BCAA oxidation was corroborated by findings from a BCKD kinase-deficient mouse model. BCKDC activity is greatly enhanced in most tissues, which correlates with markedly lower BCAA concentrations. Neurological abnormalities are prevalent in hindlimb flexion, and notably apleptic seizures occur after 6–7 months of age. The phenotype of the BCKD kinase knockout mice establishes that the tight control of BCAA oxidation is critical for normal growth and neurological functions. Conversely, the PP2Cm phosphatase has been identified as the BCKD phosphatase that binds to the BCKDC and specifically dephosphorylates the phosphoserine residue at position 293 of the E1 protein. PP2Cm-deficient mice manifested defects in BCAA oxidation and significantly produced a metabolic phenotype similar to the intermediate or intermittent MSUD. These outcomes support PP2Cm as the endogenous BCKD phosphatase, which is essential for the upregulation of BCKDC activity. The results also suggest that defects in the BCKD phosphatase may be responsible for a subset of MSUD.

The Supramolecular BCAA Metabolon

The concept that metabolic enzymes associate to form a supramolecular structure was developed over 50 years ago, which was termed 'metabolon'. The advantage of such a supramolecular assembly is to channel substrates between two juxtaposed steps in a metabolic pathway for maximal efficiency in an appropriate intracellular location. Recent studies showed that the BCATm is associated with the E1 component of human BCKDC to produce the BCAA metabolon. The dissociation constant (K_d) for the BCAA metabolon is 2.8 μM as determined by isothermal calorimetry titration. When coupled with BCATm, the k_{cat} values for the E1-catalyzed decarboxylation of BCKAs are enhanced by 12-fold. Mutations of the BCATm protein in the catalytically important CXXC center or of the E1 protein in the phosphorylation loop prevent the supramolecular complex formation. The results suggest that the formation of the BCAA metabolon can be influenced by the redox state in the mitochondrial matrix. The BCAA metabolon was further shown to contain GDH1 and some other proteins. Kinetic results suggest that GDH1 facilitates regeneration of the BCATm form that binds to the E1 protein of BCKDC. This promotes the metabolon formation, BCAA oxidation, and the cycling of nitrogen through GDH1.

Brain Neuropathology of BCKAs

The BCAAs, in particular leucine, are rapidly transported into the brain and actively metabolized. It was proposed that a leucine–glutamate cycle plays an important role in

maintaining a steady supply of glutamate, a major excitatory neurotransmitter for interneuronal communication. The BCAAs are nitrogen donors for glutamate synthesis in astrocytes, a major site of BCAA transamination, which is transferred to α -ketoglutarate to yield glutamate. This amino acid is, in turn, converted into glutamine.¹⁵ N-labeled BCAA studies showed that at least one-third of the amino groups of brain glutamate are derived from BCAAs. The BCKAs may be released from astrocytes to the extracellular fluid and taken up by neurons. Although neurons can oxidize KIC, it is preferentially re-aminated to leucine. The flux of the reverse transamination in rat cortical synaptosomes is several times greater than the rate of nitrogen transfer from leucine to glutamate. This is in contrast to the flux in astrocytes which is mainly for glutamate synthesis. In the leucine oxidative pathway, acetoacetyl-CoA is generated for ketone synthesis or for cleavage to acetyl-CoA to enter the tricarboxylic acid cycle.

In the classic form of MSUD, the excess BCAAs and BCKAs are likely to interfere with the neuronal and astrocytic metabolism. BCKAs accumulated in MSUD compromise brain energy metabolism by blocking the respiratory chain and inhibiting creatine kinase activity. Perfusion by microdialysis with leucine and KIV creates a microenvironment similar to that found in MSUD. The infusion of leucine resulted in an increase of large neutral amino acids in the extracellular space, thereby a decreased concentration in neurons. The infusion of KIC caused an 11-fold increase in leucine and two- to threefold increase in other large neutral amino acids in the extracellular space. This pattern is consistent with active transamination of KIC to leucine. These changes could affect biosynthesis of serotonin and catecholamines, and alter the homeostasis of the leucine/glutamate cycle and the glutamate/glutamine cycle in brain.

Glossary

Brassinolide The most active brassinosteroid. It affects cell elongation and division at nanomolar levels. A unique polyhydroxylated steroid with a C-6, C-7 lactone.

Gas chromatography–mass spectrometry with selected ion monitoring (GC–MS–SIM) Technique used with

deuterated standards to determine endogenous levels of brassinosteroids in plants.

Receptor kinase A signal-transduction protein with multiple domains, including an extracellular ligand-binding domain, a membrane-anchoring region, and an intracellular kinase. Numerous receptor kinases occur in various cell types in both plants and animals.

Brassinosteroids (BRs) are endogenous plant growth-promoting hormones that function at low concentrations to influence cellular expansion and proliferation, while interacting with other plant hormones and environmental factors to regulate the overall form and function of the plant. BRs are found throughout the plant kingdom in seeds, pollen, and young vegetative tissue, and the examination of the phenotype of mutants affected in BR biosynthesis or signaling provides genetic evidence that BRs are essential for normal organ elongation, vascular differentiation, male fertility, timing of senescence, and leaf development. BRs also participate in the regulation of plant responses to light, flowering time, and seed germination. They are unique among plant hormones in their close structural similarity to vertebrate and invertebrate steroid hormones, which have well-known roles in regulating embryonic and post-embryonic development and adult homeostasis in mammals and insects.

BR Structure and Natural Occurrence

BRs have been identified throughout the plant kingdom as naturally occurring compounds in monocot and dicot angiosperms, gymnosperms, algae, and pteridophytes. At least 40 free BRs and four conjugates have been rigorously characterized from plant tissue by a variety of biochemical approaches.

Discovery and Chemical Structure of Brassinolide

The discovery of brassinolide, the most active naturally occurring BR currently identified, was preceded by three decades of experiments at the United States Department of Agriculture (USDA), in which organic extracts of pollen from over 60 species were applied to a variety of crop plants to identify new compounds with growth-promoting properties. An extract from *Brassica napus* pollen was extremely potent in promoting cell elongation and division in bean second internodes and enhanced overall growth of radishes, leafy vegetables, and potatoes when young seedlings were sprayed in greenhouse experiments. USDA researchers identified the active component of the *B. napus* extract in 1979 and named the novel compound brassinolide. It was determined by single-crystal X-ray analysis to be a polyhydroxylated derivative of 5α -cholestane, namely

(22R,23R,24S)- $2\alpha,3\alpha,22,23$ -tetrahydroxy-24-methyl-B-homo-7-oxa- 5α -cholestan-6-one (Figure 1). Parallel work in a number of Japanese laboratories also identified BRs from a variety of plant tissues.

Other BRs differ from brassinolide by variations at C-2 and C-3, the presence of a ketone or de-oxo function instead of a lactone at C-6, various substitutions at C-24, and the stereochemistry of the hydroxyl groups in the side chain. Known BR conjugates include glycosylated, myristylated, and laurylated derivatives of the hydroxyls at C-2 and C-3 or in the side chain. Many BRs are biosynthetic precursors or metabolic products of brassinolide, although some of these BRs are believed to have independent biological activity in specific plants.

Endogenous Levels of BRs in the Plant Kingdom

Endogenous levels of BRs vary according to plant organ type, tissue age, and species, with pollen and immature seeds containing the highest levels, followed by young growing shoots. Pollen and immature seeds generally show BR levels of $1\text{--}100\text{ ng g}^{-1}\text{ fw}$; shoots and leaves typically have lower amounts, $0.01\text{--}0.1\text{ ng g}^{-1}\text{ fw}$. BRs are isolated from plant tissues by organic solvent extraction followed by reverse-phase high-performance liquid chromatography. Accurate quantification of endogenous levels involves spiking with deuterated forms of the BR of interest followed by gas chromatography–mass spectrometry with selected ion monitoring (GC–MS–SIM) analysis of derivatized BR samples.

BR Biosynthesis

The BR biosynthetic pathway can be divided into general sterol synthesis (cycloartenol to campesterol) and the BR-specific pathway from campesterol to brassinolide. Details of the pathway have been obtained by following the fate of labeled intermediates fed to cell-suspension cultures and whole plants, and by measuring endogenous sterol and BR levels in biosynthetic mutants blocked at various steps of the pathway.

Mevalonic Acid to Cycloartenol

Like animal steroids, BRs are products of the isoprenoid biosynthetic pathway beginning with acetyl-CoA and proceeding through intermediates such as mevalonate, isopentenyl

Figure 1 Structure of brassinolide and its sterol progenitor is compared with the animal steroid hormone testosterone and its sterol progenitor.

pyrophosphate, farnesyl pyrophosphate, and squalene-2,3-epoxide. It appears that the biosynthetic steps from mevalonate to squalene-2,3-epoxide are conserved among the phyla, but in animals and fungi squalene-2,3-epoxide is converted to lanosterol, the precursor of cholesterol, whereas in plants it is generally converted to cycloartenol, the progenitor of the plant sterols campesterol, stigmasterol, and sitosterol (Figure 1).

Cycloartenol to Campesterol

The conversion of cycloartenol to campesterol begins with C-24 alkylation of the side chain catalyzed by the enzyme sterol methyl transferase 1 (SMT1) in the presence of S-adenosylmethionine. The product, 24-methylenecycloartenol, is converted to 24-methylenelophenol in a series of steps including a C-14 sterol reductase and a Δ^7 - Δ^8 sterol isomerase, encoded in *Arabidopsis* by the *FAKEL* and *HYDRA1* genes, respectively. Mutants in the *SMT1*, *FAKEL*, and *HYDRA1* genes show dwarfism and severe defects in embryogenesis and vascular development that are not rescued by BR treatment, possibly because the early sterol pathway may produce a non-BR signaling molecule that is critical for these developmental processes.

The conversion of 24-methylenelophenol to campesterol involves a Δ^7 -C-5-desaturase, encoded by *DWARF7* (*DWF7*); a Δ^7 -sterol reductase, encoded by *DWARF5* (*DWF5*); and a C-24 sterol reductase, encoded by *DWARF1* (*DWF1*). *Arabidopsis* *dwf7*, *dwf5*, and *dwf1* mutants are intermediate dwarfs with altered vascular development and have reduced BR levels. These developmental defects can be rescued by treatment with exogenous BRs.

Campesterol to Brassinolide

In the classical pathway of BR biosynthesis, four reactions lead from campesterol to campestanol via reduction of the C-5

double bond. One of these steps requires a 5α -sterol reductase (encoded by the *DE-ETIOLATED2*, *DET2*, gene) that is an ortholog of the mammalian enzyme that catalyzes the reduced nicotinamide adenine dinucleotide phosphate (NADPH)-dependent reduction of testosterone to dihydrotestosterone. From campestanol, two biosynthetic routes are possible: early C-6 oxidation, in which a ketone is introduced at C-6 before the hydroxylation of the side chain, and late C-6 oxidation, in which the side chain is modified first and the ketone is introduced in the penultimate step. Many plants, including *Arabidopsis*, have both pathways functional, whereas others, such as tomato, appear to use only late C-6 oxidation. Hydroxylation of the side chain in either pathway occurs via successive steps involving several cytochrome P450 steroid hydroxylases, including *DWARF4* (*DWF4*). Multiple pathways from campesterol to brassinolide may occur in the same plant and brassinolide biosynthesis appears to be more of a metabolic grid than two independent linear pathways of early and late C-6 oxidation. Recent evidence also suggests that C-22 hydroxylation of campesterol by *DWF4* most likely occurs before the C-5 reduction catalyzed by *DET2*. The most direct biosynthetic route from campesterol to brassinolide, based on current experimental evidence, is shown in Figure 2.

The *det2* and *dwf4* mutants of *Arabidopsis* are extremely dwarf in stature; have dark-green, rounded, and downward-curling leaves; and exhibit a prolonged life span with reduced fertility and altered vascular development. In the dark, these mutants show some of the features of light-grown plants, including shortened hypocotyls and open cotyledons. All these phenotypic alterations can be rescued to wild type by exogenous application of brassinolide or BR intermediates downstream of the biosynthetic block caused by the mutant. Altering *DWF4* gene expression in *Arabidopsis* and rice results in altered plant growth and development, providing further evidence of the importance of regulating BR biosynthesis for normal plant growth.

Figure 2 Biosynthetic pathway leading from the plant sterol campesterol to brassinolide. From campestanol, multiple alternative pathways exist and several points of interconnection are possible between the pathways. The most direct biosynthetic route based on recent experimental evidence is shown. DET2 is a steroid 5- α reductase and various CYP proteins are cytochrome P450 enzymes.

BR Physiology

BRs have a dramatic positive effect on stem elongation, promoting epicotyl, hypocotyl, and peduncle elongation in dicots and enhancing coleoptile and mesocotyl growth in monocots. Exogenous BRs also stimulate tracheary element differentiation and numerous studies *in vivo* suggest that endogenous BRs are essential for normal vascular development. In many systems, BRs increase rates of cell division, particularly under conditions of limiting auxin and cytokinin. BRs also promote seed germination, accelerate senescence, cause hyperpolarization of membranes, stimulate ATPase activity, and alter the orientation of cortical microtubules. In addition to effects on growth, BRs also mediate the effects of abiotic and biotic stresses, including salt and drought stress, temperature extremes, and pathogen attack.

BR Signal Transduction

Recently, it has been shown that animal steroids can be recognized by cell-surface receptors. However, the classic signaling pathway for these hormones involves binding the steroid to an intracellular receptor consisting of a variable N-terminal domain, a highly conserved DNA-binding domain with two zinc fingers, and a multifunctional domain that mediates ligand binding, dimerization, and ligand-dependent transcriptional activation. The completed genome sequence of *Arabidopsis thaliana* indicates that plants do not contain members of this superfamily of intracellular steroid receptors, suggesting that cell-surface recognition is the primary, if not only, form of plant steroid perception. Thus, plant and animal steroid hormones share many structural and functional features, but differ in their primary signaling pathways.

Receptor Kinases and BR Perception

The best-characterized component of BR signal transduction is *BRASSINOSTEROIDINSENSITIVE 1 (BRI1)*, a single genetic locus in *Arabidopsis* encoding a leucine-rich repeat (LRR) receptor kinase. Homologous genes have been identified in rice, tomato, and pea. Numerous *bri1* mutant alleles have been identified by various genetic screens, most of which exhibit the extreme dwarfism and other phenotypic characteristics of severe BR-deficient mutants. In contrast to the biosynthetic mutants, *bri1* mutants cannot be rescued by BR treatment, consistent with their role in signal transduction.

The BRI1 protein consists of a putative signal peptide followed by the extracellular domain proper including a leucine zipper and 25 LRRs that are flanked by short sequences containing paired cysteines. A 70-amino-acid island that is critical

for biological function is embedded between repeats 21 and 22. Downstream of the extracellular domain lies a short hydrophobic single-pass transmembrane domain, followed by the juxtamembrane region and the cytoplasmic kinase domain. Binding studies with radiolabeled brassinolide and microsomal fractions of wild-type, mutant, and transgenic *Arabidopsis* plants clearly showed that BRI1 is an essential component of the BR-receptor complex. Subsequent experiments using photo affinity-labeled BRs demonstrated that BR binds directly to BRI1 without an intermediate accessory protein. The 70-amino-acid island domain in conjunction with the adjacent C-terminal LRR was necessary and sufficient for BL binding, thus defining a novel 94-amino-acid plant steroid-binding motif.

The mechanism of action of many animal receptor kinases involves ligand-mediated homo- or heterodimerization of the

Figure 3 A model for BR signal transduction in *Arabidopsis*. BR binds to the BRI1 receptor kinase, activating the intracellular kinase domain, which releases the negative regulator BK1 and allows the BRI1/BAK1 heterotetramer to form. Sequential transphosphorylation of the BRI1/BAK1 pair results in downstream phosphorylation of BSK1, which then interacts with and activates the BSU1 phosphatase. BSU1 removes Tyr-200 of the negative regulatory kinase, BIN2, inactivating it and allowing the unphosphorylated forms of the BES1/BZR1 transcription factors to accumulate in the nucleus where they regulate the expression of genes associated with the BR response.

receptor followed by autophosphorylation of the intracellular kinase domain. This activation of the kinase results in the recognition and phosphorylation of downstream signaling components, leading ultimately to the regulation of specific gene expression. Plant receptor kinases appear to follow the same general paradigm of receptor kinase action, and mutational analysis shows that both a functional extracellular domain and an active cytoplasmic kinase are essential for BRI1 function. Identification of BRI1 phosphorylation sites by mass spectrometry followed by a functional analysis of their biochemical and biological significance, clearly demonstrated that phosphorylation plays a key role in BRI1 function.

Recent evidence also confirms that oligomerization with another LRR receptor kinase plays an important role in BR signaling. BAK1 (BRI1 ASSOCIATED RECEPTOR KINASE 1) shares similar structural organization to BRI1 except that it has only five LRRs in its extracellular domain and lacks the 70-amino-acid island of BRI1. BAK1 is expressed in all tissues of the plant, similar to the global expression pattern of BRI1, and confocal laser microscopy of transgenic plants expressing fusion proteins shows plasma membrane as well as endosomal membrane localization for both BRI1 and BAK1. Direct physical interaction between BRI1 and BAK1 was confirmed in yeast cells, plant protoplasts, and whole *Arabidopsis* plants by a variety of biochemical approaches. Moreover, genetic studies strongly suggest that BAK1 plays an important role in BR signaling. A detailed dissection of the BRI1/BAK1 interaction resulted in the sequential transphosphorylation model of BR signaling, in which BRI1 controls signaling specificity by direct BR binding followed by downstream substrate phosphorylation. The co-receptor BAK1 is then activated by BRI1-dependent transphosphorylation and subsequently enhances signaling output through reciprocal BRI1 transphosphorylation. This model suggests both conservation and distinct differences between the molecular mechanisms regulating phosphorylation-dependent receptor kinase activation in plants and animals.

Downstream Components

Besides BAK1, several other BRI1-interacting proteins have been identified with important functions in BR signal transduction. BKI1 (BRI1 KINASE INHIBITOR 1) is a negative regulator of BR signaling which binds to BRI1 and is membrane associated in the absence of BR. BR binding to BRI1 causes dissociation of BKI1 from the membrane, which releases repression of the pathway by allowing BRI1 and BAK1 to hetero-oligomerize to initiate BR signaling. Another membrane-associated BRI1-interacting protein, BSK1 (BR SIGNALING KINASE 1), is a positive regulator of BR signaling which belongs to the cytoplasmic receptor-like kinase (RLCK) subfamily containing an N-terminal kinase domain and a C-terminal tetratricopeptide motif. BR-dependent phosphorylation of BSK1 by BRI1 allows

BSK1 to interact with another positive regulator of BR signaling, BSU1 (BRI1 SUPPRESSOR 1), a protein phosphatase that propagates the BR signal downstream by dephosphorylating and in activating a downstream negative regulator of BR signaling, the BIN2 (BRASSINOSTEROID INSENSITIVE 2) kinase.

BIN2, which is homologous to insect and mammalian shaggy-like kinases involved in the Wntless/Wnt-signaling pathways, acts by phosphorylating two related transcription factors, BZR1 and BES1. Phosphorylation by BIN2 targets BZR1 and BES1 for proteasome-mediated degradation, inhibits binding to promoters of BR-regulated genes, and promotes binding to 14–3–3 proteins resulting in cytoplasmic retention of the transcription factors. In the presence of BR, BIN2 activity is inhibited by BSU1 dephosphorylation on Tyr-200 and the nonphosphorylated forms of BZR1 and BES1 accumulate in the nucleus where they interact with other transcription factors to regulate the expression of specific genes involved in the BR response. Microarray analyses have identified hundreds of BR-regulated genes including those encoding wall-modifying proteins involved in cell expansion, genes regulating cell division, and numerous transcription factors including those also regulated by the plant growth-promoting hormone, auxin. BR signal transduction has become one of the best-studied plant-signaling pathways involving receptor kinase action. Our current knowledge of BR signal transduction is summarized in [Figure 3](#).

Glossary

Adaptor proteins Cytosolic proteins that link membrane proteins to signaling and cytoskeletal complexes and allow for regulation of physiological responses. In the example of cell-adhesion proteins, adaptor proteins (catenins) provide the linkage between cell adhesion transmembrane proteins and the cytoskeleton.

Cell–cell adhesion Process of establishment and maintenance of contacts between adjacent cells in tissues and organs of multicellular organisms.

Cell–cell adhesion molecules Transmembrane glycoproteins that mediate cell–cell binding. There are three major protein families: the cadherin superfamily, the immunoglobulin superfamily, and selectins.

Cell–cell junctions Specialized regions on the cell surface through which cells are joined to each other. Tight junctions in epithelial cell layers form a ribbon-like seal between compartments. Gap junctions are protein-lined channels between two cells that allow diffusion of small molecules from one cell to the next. Adherens junctions and desmosomes are dense protein plaques connected to cytoskeletal networks that link two adjacent cells.

Cytoskeleton Network of fibrous proteins found in the cytosol of cells that provides structural support for the cell, determines cell shape and motility, and allows directional movement of organelles and vesicles inside the cell. There are three major classes of cytoskeletal filaments: actin microfilaments, microtubules, and intermediate filaments.

Cadherin Superfamily

Cell–cell adhesion complexes are essential for the organization and maintenance of complex tissues in multicellular organisms. Proteins that participate in cell–cell adhesion include the cadherin superfamily, the immunoglobulin superfamily, and selectins. The cadherin superfamily comprises transmembrane glycoproteins found in all metazoa, and shares a conserved extracellular domain that contains many calcium-binding domains. The four major subfamilies include classical cadherins, desmosomal cadherins, protocadherins, and atypical cadherins.

Classical Cadherins (type I and II)

The classical cadherins are characterized in terms of structure, mechanism of adhesion, and function. They generally have five extracellular repeats (EC 1–5), a single transmembrane domain, and an intracellular domain that binds the adaptor proteins β -catenin, γ -catenin, p120, and hankai (Figure 1). β -Catenin binds α -catenin that directly or indirectly interacts with the actin cytoskeleton. Classical cadherins are classified as type I or type II depending on the adaptor proteins that bind to the cytoplasmic domain.

While expressed broadly in all tissues, some classical cadherin subtypes are more abundant in specific tissue types than in others (e.g., epithelial, E-cadherin; nervous, N-cadherin; placenta, and P-cadherin), but, generally, multiple forms are expressed in different ratios in the same tissue. Classical cadherins mostly form homophilic bonds, such as E-cadherin with E-cadherin on the adjacent cell, but heterophilic interactions also occur. Classical cadherins cluster along the plasma membrane, forming an adhesion complex known as the ‘adherens junction’ (AJ). Nectins, a class of immunoglobulin G (IgG) superfamily cell–cell adhesion proteins, localize there as well and contribute to the formation and maintenance of the cell–cell adhesion complex. Classical cadherins are spatially and temporally regulated throughout development and are crucial for the formation of cell layers and complex tissue structures.

Desmosomal Cadherins

Desmosomal cadherins are the major components of the desmosome, a dense adhesion complex required for tissues to withstand mechanical stress. There are two types of desmosomal cadherins with multiple isoforms and splice variants: desmogleins (1–4) and desmocollins (1–3; a and b). Desmosomal cadherins are thought to form heterophilic bonds between desmoglein and desmocollin, but there is also evidence for

Figure 1 Members of the cadherin superfamily. Classical and desmosomal cadherins contain EC1–5 domains with a tryptophan at position 2 (W2). Whereas desmosomal cadherins have a similar extracellular domain to classical cadherins, their cytoplasmic domain differs. There are two types of desmosomal cadherins: desmoglein (Dsg) and two splice variants of desmocollin (Dsc a,b). Protocadherins, such as the β subtype, have varying numbers of cadherin domains, marked by [X]. Atypical cadherins contain cadherin domains but share no other commonalities with other cadherin subtypes. One example, flamingo, names after its Flamingo Box, is a seven-pass transmembrane protein.

homophilic interactions. Apart from the type 2 isoforms, desmosomal cadherins are only expressed in stratified epithelia, in a differentiation-specific manner within the layers of the epidermis. Similar to classical cadherins, desmosomal cadherins have five EC repeats, a single transmembrane domain, and an intracellular domain that binds to adaptor proteins (Figure 1). The structural organization of desmosomes is well defined. Plakoglobin and plakophilin bind to the cytoplasmic domain of cadherins, and desmoplakin links the complex to the intermediate filament cytoskeleton. The desmosomal complex is present in most higher metazoa, with the exception of *Drosophila* and *Caenorhabditis elegans*. While the classical cadherin-containing AJ is typically established first upon cell–cell contact and during development, the desmosome is essential for maintaining strong intercellular adhesion and resisting shearing stress across a tissue.

Protocadherins and Atypical Cadherins

The largest cadherin subfamily is the protocadherins, which consists of more than 50 subtypes. Three exons encode a ‘constant’ region, which is family specific and cytoplasmic. The other part of the protein is encoded by a single large ‘variable’ exon. The combination of the intracellular ‘constant’ and ‘variable’ extracellular domains provides potentially thousands of combinations, similar to immunoglobulin proteins. Protocadherins are most commonly found in the nervous system and their diversity may contribute to nervous system development and organization. While there is evidence for homophilic binding, the regulation and strength of protocadherins is most likely

different from classical cadherins. Heterophilic binding may prove more important for protocadherin interactions. A few binding partners have been identified, among them Fyn kinase.

Atypical cadherins contain one or more cadherin-like extracellular repeat domains but have no other resemblance to the other cadherins. The atypical subfamily includes Fat-like, seven-pass transmembrane (flamingo), and the Dcad102F-like cadherins. They do not appear to participate in cell–cell adhesion but rather in different signaling pathways, including planar cell polarity (PCP), Dpp and Hippo pathways. A summary of the structural differences between the subfamilies is shown in Figure 1.

Regulation of Cadherin Adhesion

Cadherin proteins have two major structural and functional domains: the extracellular domain, which binds to another cadherin on an adjacent cell; and the cytoplasmic domain, which binds cytosolic adaptor proteins that link the complex to the cytoskeleton. The exact mechanism how cadherins achieve cell–cell adhesion is still an area of much research. Most knowledge comes from studies on the classical and desmosomal cadherins, and therefore this article will focus on them.

Role of the Extracellular Domain

Extracellular domain structure

The extracellular domain of cadherins is characterized by the ECs. Three calcium molecules bind successively between the repeats, giving the protein a curved structure and rigidifying it.

A specific binding structure of these tandem repeats has been hypothesized based on the recent crystal structure of the entire ectodomain of C-cadherin (classical cadherin). The structure suggests the importance of the tryptophan at position two (W2) in the EC1 domain, which is conserved in both classical and desmosomal cadherins (Figure 1). This residue contributes to the formation of a strand-swapped dimer, connecting two opposing cadherin EC1 domains in a *trans* configuration. Mutations in the W2 residue result in lethality in zebrafish (termed the *glass onion* mutant) and substitution with alanine (W2A) results in loss of Ca^{2+} -dependent, cadherin-mediated cell–cell adhesion. There is also the possibility of a lateral *cis* dimer between cadherins on the same cell, although it is likely to be close to the same interface as the *trans* interaction. Additional crystal-structure studies reveal a second configuration, termed the ‘X dimer’ that is mediated by residues near the EC1–EC2 calcium-binding sites and is thought to be an intermediate that facilitates the final EC1–EC1 *trans*-dimer.

In contrast to the AJ, desmosomes have an electron-dense midline between the intercellular space and the plasma membrane. The appearance of a midline appears to correlate with a hyper-adhesive and Ca^{2+} -independent state of desmosome adhesion. Desmosomes in embryonic tissue and wounded epithelia are Ca^{2+} dependent and most often do not form such a midline. Three-dimensional reconstructions based on electron-microscopy-tomography images and X-ray-crystal structures of C-cadherin have been used to examine the structure of the extracellular intermolecular interface. Two possible explanations have been proposed: desmosomal cadherins undergo a locking mechanism that creates a periodic arrangement, trapping Ca^{2+} , and resulting in strong extracellular Ca^{2+} -independent adhesive properties, or the desmosomal cadherins form a series of densely tangled knots with no regular structure. A crystal structure has not yet been obtained for desmosomal cadherins.

Mechanisms of cadherin specificity in cell sorting

Initial experiments conducted on classical cadherins demonstrated that cells expressing specific cadherin subtypes segregate into homotypic aggregates when mixed. During development of certain tissues, expression levels of cadherin subtypes switch, indicating that specific combinations of cadherins are important for cell–cell adhesion and proper development. However, additional studies using cadherin-coated beads or cadherin-transfected cells in aggregation assays show promiscuity in cadherin-subtype interactions, suggesting that, for at least a subclass of cadherins, homotypic binding is not as strict as previously thought. Several factors, such as the level of expression on the cell surface and the level of shear force during mixing, affects adhesion specificity. Affinity differences between cadherins can explain the dependence on shear forces.

By contrast, desmosomal cadherins are traditionally thought to form heterotypic adhesion (e.g., desmoglein–desmocollin). Both desmocollin and desmoglein are necessary for strong cell–cell adhesion but the specific interactions of these cadherins remains unclear. Biochemical studies with purified desmosomal cadherins show heterophilic and homophilic interactions, assessed using Biacore and single-molecule atomic-force microscopy. A more comprehensive analysis of desmosomal cadherin interactions will need to be conducted with all possible combinations under the same experimental conditions.

Role of the Cytoplasmic Domain

Linkage of cadherin to adaptor proteins

The cytoplasmic domain of classical and desmosomal cadherins recruits cytoplasmic adaptor proteins that belong to the catenin family: β -catenin, plakoglobin (γ -catenin), and p120. Typically, classical cadherins bind β -catenin, which, in turn, binds another catenin family member, α -catenin. α -Catenin is a monomer or homodimer, and *in vitro* reconstitution studies show that monomeric and dimeric α -catenin have different binding specificities. Monomeric α -catenin binds to β -catenin but the α -catenin homodimer cannot and instead, the homodimer has a higher affinity for F-actin.

p120 and hakai bind directly to the juxtamembrane domain of classical cadherins and controls cadherin turnover. Plakoglobin, a homolog of β -catenin, can bind to type I classical cadherins but is most often outcompeted by β -catenin due to weaker affinity for the cadherin cytoplasmic domain. Desmosomal cadherins, on the other hand, bind plakoglobin (not β -catenin) and catenin-related proteins called ‘plakophilins’ (Pkp1–3). The cytoplasmic domain of the desmosomal cadherins bind to plakoglobin and plakophilin binds to a plakin protein called ‘desmoplakin’. Plakin proteins are cytolinkers, and in the case of desmoplakin, link the desmosome complex to intermediate filaments. The cadherin complexes are depicted in Figure 2.

Linkage to the cytoskeleton

During cell–cell adhesion, cadherin–catenin complexes cluster together and cell–cell adhesion strengthens. How classical cadherin complexes are linked to the actin cytoskeleton is currently an area of debate. Actin near the complex is bundled; α -catenin homodimers most likely participate in the bundling of actin filaments, and also inhibit the Arp2/3 complex and actin branching. Mechanosensing studies show an important link between the complex and the cytoskeleton, but the mode remains unclear. Most likely, more proteins are involved in the regulation of the actin cytoskeleton by the cadherin complex.

Linkage between the cytoskeleton and desmosomes has been investigated using desmoplakin mutants. Deletion of the N-terminal domain of desmoplakin results in desmosomal complexes that have lost their connection to intermediate filaments, and, as a result, desmosomal and classical cadherin complexes intermix. The crystal structure of desmoplakin indicates a possible intermediate filament-binding domain. Intermediate filaments are less dynamic than actin and are thought to add stability and rigidity to the desmosomal complex, as well as provide physical and spatial separation from other adhesion complexes.

Adhesion complex turnover

Cadherin complex assembly and disassembly is a highly regulated process and can be regulated through phosphorylation of cadherin or β -catenin on serine/threonine and tyrosine residues. Phosphorylation affects their binding affinity for one another. Serine/threonine phosphorylation stabilizes the cadherin/catenin complex, thereby strengthening adhesion. Conversely, tyrosine phosphorylation of either cadherin or β -catenin destabilizes their bond and weakens adhesion. Although the mechanism is unclear, p120 also seems to participate in the regulation of cadherin endocytosis.

Figure 2 The adherens junction and desmosome. Top: Classical cadherins bind to one another across intracellular space (between two adjacent cells) and assemble into a complex known as the adherens junction. The cytoplasmic side of cadherins binds to β -catenin (β). β -Catenin then binds α -catenin (α), creating a ternary complex at the membrane. α -Catenin can form a homodimer, which does not bind β -catenin, but has a high affinity for F-actin and promotes actin bundling. How the α -catenin monomer and homodimer are regulated is not known. Below: Two types of desmosomal cadherins bind one another to assemble the desmosome, a dense adhesion complex. The cytoplasmic domain of desmosomal cadherins binds the catenins, plakoglobin (Pg), and plakophilin (Pkp). Desmoplakin (Dp) facilitates the binding of the complex to intermediate filaments.

Desmosomal turnover is less well understood. Within the epidermis, desmosomal cadherin subtypes have specific expression patterns. The change in distribution could be due to exchange of molecules or replacement of existing desmosomes as cells move up layers in the epidermis. In addition, the organization of desmosomes is disrupted in wounded epithelia, possibly due to protein kinase C, making the complex more extracellular- Ca^{2+} dependent and increasing its turnover rate. Whole desmosomal complexes can also be internalized as a faster means of weakening adhesion.

Functions in signaling

A number of the adaptor proteins bound to adhesion complexes also participate in signaling events. β -Catenin, plakoglobin, and p120 function as coactivators for the lymphoid enhancer-binding factor/Tcf (LEF/Tcf) family of transcription cofactors, downstream of Wnt signaling. Plakophilins are described as multifunctional scaffolds for signaling proteins at the plasma membrane. For example, plakophilin-2 is implicated in signaling pathways that regulate junction assembly, Rho-mediated actin remodeling, and transcriptional activity. It remains unclear, if the different roles for these catenin proteins are independent or regulated with respect to one another.

Role of Cadherins in Development and Disease

Cell and Tissue Morphogenesis

As discussed above, classical cadherins can sort cells based on their expression levels; it is thought that during development cell populations sort out from each other using a similar mechanism. Most of the information about the morphogenic roles of different cadherins is based on genetic deletions in mice ([Table 1](#)). Knockout of the E-cadherin gene produces the most severe phenotype with early embryonic lethality at the time of implantation due to lack of formation of the trophoblast and blastocyst cavity. Although E-cadherin is essential for development of the blastocyst, knockout of N-cadherin leads to heart defects and malformation of the neural tube, resulting in embryonic lethality at days 9–10. The developmental defects are attributed to loss of adhesion, but the distinction between the classical cadherin subtypes suggests a role for cadherins in determining cell fate as well. Similarly, loss of classical cadherin-associated adaptor proteins also causes embryonic lethality, although β -catenin knockout embryos survive implantation unlike those in which α E-catenin is deleted. This difference is due to replacement of β -catenin by plakoglobin and the loss of Wnt signaling after implantation, resulting in a failure in mesoderm formation.

Table 1 Effects of gene deletions of selected cadherins and adhesion components on mouse development

<i>Gene/protein</i>	<i>Subfamily</i>	<i>Gene defect</i>	<i>Phenotype</i>
<i>E-cadherin</i>	Classical	Knockout, deletion of extracellular Ca^{2+} -binding and adhesion motif	Embryonic lethal at time of implantation, embryonic compaction occurs, probably due to maternally deposited E-cadherin, but embryos fail to form trophectoderm or blastocyst cavity.
<i>N-cadherin</i>	Classical	Knockout	Embryonic lethal E9–10, major heart defects, and malformed neural tube and somites.
β -catenin	AJ component	Knockout	Embryonic lethal E7–9, at day 7 cells detach from ectodermal cell layer, the three germ layers and amniotic folds fail to form, and epithelial organization of ectoderm is completely lost.
α -E-catenin	AJ component	Gene trap insertion deleting carboxyterminal portion	Embryonic lethal at time of implantation, failure to form the trophoblast epithelium
Dsc-1	Desmosomal	Knockout	Normal at birth, epidermal fragility (flaking) and barrier defects, hyperproliferation and abnormal differentiation of epidermis, and hair loss.
Dsc-3	Desmosomal	Knockout	Lethal before implantation.
Dsg-2	Desmosomal	Knockout	Embryonic lethal shortly after implantation. Decreased embryonic-stem-cell proliferation.
Dsg-3	Desmosomal	Knockout	Normal at birth, disintegration of epidermis (acantholysis), hair loss, and runting (probably due to erosions in oral mucosa).
<i>Plakoglobin</i>	Desmosome Component	Knockout	Embryonic lethal E10.5–15 due to heart failure. Some genetic backgrounds have delayed embryonic lethality with epidermal blistering due to abnormal desmosome structure and loss of IF association.
<i>Desmoplakin</i>	Desmosome Component	Knockout	Embryonic lethal E6.5 due to defects in extra-embryonic tissues and failure of egg-cylinder expansion, abnormal desmosomes. Reduction in number and size of desmosomes and abnormal structure.

Desmosomes also play an important role during development, although certain desmosomal cadherin isoforms appear to be less essential. Deletion of some desmosomal cadherins leads to early lethality due to heart defects, whereas other knockouts produce viable offspring with skin abnormalities. Although deletion of desmocollin-3 causes pre-implantation lethality, certain mutations in the gene result in skin defects in postnatal pups. Knockout of desmoglein-2 also causes death shortly after implantation, most likely due to decreased embryonic-stem-cell proliferation.

It should be noted that cell–cell adhesion is crucial for normal development because cadherins also play an important role in the functional polarization of epithelial cells. Structurally, the formation of cadherin-mediated adhesion complexes and tight junctions, another cell–cell junction, establishes a cell monolayer (often a simple epithelium) that separates two biological compartments. The epithelial monolayer comprises cells with structurally and functionally different plasma-membrane domains (termed ‘apical’ and ‘basolateral’), and creates a barrier that maintains homeostasis by regulating the movement of proteins, solutes, and ions across and between cells.

As mentioned previously, atypical cadherins, such as flamingo, establish a different kind of polarity (PCP) across the cell populations, for example, in producing left/right asymmetry in the ommatidia of the *Drosophila* eye (Figure 1).

Consequences of Disruption of Cadherin Function: Cancer and Disease States

A hallmark of cancer is the loss of epithelial phenotypes, such as cell–cell adhesion along with changes in cytoskeletal organization. These changes are accompanied by an increase in

expression of proteins most common in mesenchymal cells, such as vimentin. This switch, known as the epithelial-to-mesenchymal transition (EMT), positively correlates with increased tumor invasiveness. In order for metastasis to occur, primary tumor cells must egress from the original tumor mass and migrate to other sites within the body. EMT also includes a switch in the subtype of classical cadherin, in which E-cadherin levels decrease whereas N-cadherin levels increase. This switch, combined with only partial loss of junctional components, may facilitate the transition from mesenchymal- back to epithelial-type cells (MET), and, ultimately the progression from a micro-metastases to full metastases.

Remodeling of desmosomes may also play an important role in tumor growth, invasion, and metastasis. Introduction of desmosomal proteins into invasive cells induces aggregation and decreases their invasiveness. Similar to AJ proteins, complete loss of all desmosomal proteins does not occur in metastatic tumors. Currently, however, it is unclear what part desmosomes play in EMT, metastasis, and MET.

Mutations in desmosomal components have been identified as the cause of a number of hereditary diseases. Several heart defects, such as arrhythmogenic right-ventricular cardiomyopathy (ARVC), result from mutations in plakoglobin, desmoplakin, or Pkp2. By contrast, mutations in Pkp1, Dsg1, Dsg4, or specific domains of desmoplakin cause defects in skin development. Skin defects manifest as skin fragility, blistering, or epidermal thickening, depending on the mutation. The variation in skin and heart defects suggests that each desmosomal protein has a cell-type-specific role in cell differentiation and tissue patterning. To date, no human mutations have been identified in desmocollins. In addition, an autoimmune disease called ‘pemphigus’, targets desmosomal cadherins and

causes loss of cell–cell adhesion in the epidermis and mucus membranes. The area affected depends on the isoform targeted by the autoantibodies and results in severe blistering.

In summary, cadherin-mediated cell–cell adhesion is crucial for normal development, tissue organization and establishing cell polarity. Abnormalities in cadherins or cadherin-binding proteins result in disease states, such as cancer. Many questions still remain regarding how adhesion complexes are regulated and their roles in cytoskeletal rearrangement.

Glossary

Adherens junction Cadherin-dependent adhesive structures, linked to the actin cytoskeleton, that mediate attachment of cells to one another.

Cadherins Family of homophilic adhesion molecules that mediate Ca^{2+} -dependent cell–cell adhesion.

Catenins Family of proteins comprising α -, β -, γ -, and p120 catenin, that attach to the cytoplasmic tails of cadherins.

Homophilic The preference of a molecule for interactions with identical molecules.

Rho family GTPases Family of regulatory proteins that act as molecular switches, alternating between active and inactive forms.

The Cadherin Family

The cadherin superfamily comprises several subfamilies, including classic cadherins, atypical cadherins, desmocollins, desmogleins, protocadherins, Fat, and Flamingo cadherins.

Classic Cadherins

Classic cadherins, which comprise 26 members in humans, like E-, N-, and P-cadherin, are components of adherens junctions between cells. The most highly characterized is E-cadherin, which is predominantly expressed in epithelium. The classic cadherins are single-span transmembrane proteins with a highly conserved carboxy-terminal cytoplasmic domain and five extracellular domains, termed cadherin repeats. Ca^{2+} binding to the extracellular domain induces homophilic adhesion with cadherin molecules on adjacent cells. The cytoplasmic tail of cadherin associates with the actin cytoskeleton via proteins called catenins. Cadherin binds β -catenin or γ -catenin (also termed plakoglobin), which in turn bind to α -catenin (Figure 1). The interaction of α -catenin with the actin cytoskeleton is thought to strengthen the intercellular adherens junction. Another catenin, termed p120^{cas}, also binds to the cadherin tail in the cytoplasm. The closely related type II cadherins (e.g., VE-cadherin) have similar properties.

Desmosomal Cadherins

Desmocollins and desmogleins are components of desmosomes, which are sites of cell–cell adhesion in tissues subjected to mechanical strain (e.g., epidermis and the myocardium). The overall structure of these desmosomal cadherins resembles that of the classical cadherins, but their cytoplasmic tails are linked to the intermediate filaments of the cytoskeleton.

Protocadherins

The protocadherin family members have as many as seven extracellular Ca^{2+} -binding domains, a transmembrane region, and divergent cytoplasmic domains. They appear to participate in development and may have a particularly important role in the central nervous system.

Other Cadherins

Other cadherins range from those with seven transmembrane segments (such as Flamingo) to T-cadherin, which lacks both transmembrane and cytoplasmic regions.

Functions of Cadherin Signaling

Originally described exclusively as cell adhesion proteins, cadherins have been shown to influence multiple aspects of cell behavior. Indeed, cadherins can transmit signals across the cellular membrane into the interior to modulate cell function. While many members of the cadherin family are likely to share this capacity, to date only members of the classic cadherin family have been studied in detail and they are the focus of this article.

Signaling Triggered by Cell–Cell Contact

Signaling can be triggered when cadherins attach to other cadherins on adjacent cells, allowing information about the external environment to be conveyed into the cell. For example, most normal cells grown in culture dishes will reproduce until they form a single continuous layer. A process known as ‘contact inhibition’ then prevents further cell division. Cadherin–cadherin junctions between cells produce a signal that leads to contact inhibition and renders the cells insensitive to the stimulatory effects of growth factors. Signals generated by interactions between cadherins are also implicated in the formation of desmosomal cell junctions, nerve outgrowth, establishment of cell polarity, cytoskeletal organization, tissue formation, cell differentiation, cell movement, and regulation of gene expression.

Influence of Cadherin Level on Signaling

The amount of cadherin present on the cell surface may influence the signals generated. For example, expression of high levels of E-cadherin can inhibit cell motility and cell division and induce cell polarity. These effects have led to the description of E-cadherin as a tumor suppressor. In fact, loss of functional E-cadherin is often associated with epithelial tumor

Figure 1 Schematic model of a cadherin-mediated adherens junction. Cadherins on adjacent cells interact with one another to provide intercellular adhesion. The terminal portion of the cytoplasmic tail of cadherin binds to β -catenin (β -ctn) or γ -catenin (not shown), which in turn binds to α -catenin (α -ctn). The interaction of α -catenin with the actin cytoskeleton stabilizes the adherens junction. Another catenin, p120^{ctn} (p120), stabilizes cadherin–catenin complexes by interacting with the cytoplasmic portion of the cadherin tail near the cell membrane.

progression and invasion. Reduced E-cadherin expression is mediated by mutation, aberrant internalization, or transcriptional regulation. Regulation of E-cadherin gene transcription alters the total amount of E-cadherin protein in cells during morphogenic processes such as hair follicle development. The level of E-cadherin on the cell surface also can be specifically regulated. These changes are likely to modulate not only the adhesive properties of the cell, but also the signals that the cell receives through contacts with other cells. In some cases, alterations in the level of cadherin may regulate cellular function even in the absence of cadherin–cadherin interactions between cells.

Different Signaling Properties of Various Cadherins

It is notable that the different types of cadherins induce different changes in cell behavior. For example, while E-cadherin usually reduces the motility of a cell, the presence of N-cadherin or cadherin-11 has the opposite effect, enhancing the ability of cells to crawl over surfaces and invade tissue. It is clear that the various cadherins trigger different signaling pathways. These differences are likely to play a crucial role in the regulated changes in cell behavior that occur during early animal development (embryogenesis). A striking example of this sort of change occurs when cells undergo epithelial–mesenchymal transitions. This process occurs during tissue remodeling when relatively sedentary epithelial cells with stable adherens

junctions transform into more motile and invasive mesenchymal cells in order to migrate and form new tissue structures. These events are frequently accompanied by a switch in cadherin expression, for example, from E-cadherin to N-cadherin. Similar changes occur during malignant transformation. Most human cancers arise from epithelial cells. These cells normally express E-cadherin. In many cases, expression of functional E-cadherin is lost during malignant transformation, and anomalous expression of N-cadherin or cadherin-11 occurs. These changes may contribute to the increased growth rate, and increased migratory and invasive capacity of cancer cells.

Inside-Out Cadherin Signaling

It is also apparent that the adhesiveness of cell-surface cadherins can be modulated from within the cell in the absence of changes in the level of cadherin expression. Therefore, cadherins are able to transduce both outside-in and inside-out signals. Feedback between these two types of signals is crucial to allow the correct formation and disassembly of cadherin–cadherin junctions during morphogenesis and for the continuous remodeling of adherens junctions that occurs even in sedentary cells.

Mechanisms of Cadherin Signaling

Considerable progress has been made in describing cadherin signaling. Classic cadherins interact with several signaling molecules, but the molecular mechanisms that constitute the signaling pathways are not completely understood. Three major signaling pathways have been described.

Rho Family GTPase Signaling

An important target of cadherin signaling is the cytoskeleton. This dynamic scaffold of rod-like actin must be rearranged to allow cells to form junctions with other cells and for cells to move. Members of the Rho family of small guanosine triphosphatases (GTPases) are vital regulators of these events and they are activated in response to the formation of cadherin-mediated cell junctions. Changes in the activity of the Rho family GTPases also lead to alterations in the adhesive capacity of cadherins. Thus, communication between cadherin and Rho GTPases is bidirectional. In general, GTPases serve as switches that are on when bound to GTP and off when the bound GTP is hydrolyzed to guanosine diphosphate (GDP). The best-characterized members of the Rho family are Cdc42, Rac1, and RhoA.

Rac1 is activated rapidly in response to cadherin binding (Figure 2). Active Rac1 stimulates remodeling of the actin cytoskeleton that leads to the formation of cell membrane protrusions known as ‘lamellipodia’. This change in morphology may help extend the contact zone between cells, enhancing formation of stable adherens junctions.

Cdc42 induces the formation of filopodia or microspikes, small finger-like projections from the cell, that are needed for the first steps of adherens junction formation by cadherins. Cdc42 is activated upon the assembly of E-cadherin-mediated cell junctions (Figure 2). This mechanism perhaps allows

E-cadherin to initiate signals that in turn further stimulate adherens junction formation. Cdc42 also activates the so-called partitioning defective (PAR)/atypical protein-kinase (aPKC) complex and thereby stimulates cell polarity and tight junction formation.

Activated Cdc42 or Rac1 can also influence the function of a protein known as 'IQGAP1'. High levels of IQGAP1 in a cell decrease E-cadherin-mediated adhesion, perhaps by binding β -catenin, thus displacing α -catenin from the E-cadherin- β -catenin complex. Activated Cdc42 or Rac1 can bind to IQGAP1 and counteract this activity, thereby increasing the adhesive capacity of cadherins.

Activation of RhoA leads to the formation of stress fibers. Active RhoA influences E-cadherin function and appears necessary to promote the formation of contractile actin bundles for maturation of adherens junctions. Moreover, cadherin signals can modulate the activity of RhoA. For example, RhoA activity is decreased as cells become confluent. Thus, cadherin can regulate the actin cytoskeleton by multiple mechanisms.

The transition from the off to the on state of GTPases can be brought about by guanine nucleotide exchange factors (GEFs) that cause the displacement of GDP from the GTPase, and replacement with GTP. Conversely, GTPase activating proteins (GAPs) enhance the conversion of GTP to GDP, so inactivating the GTPase. It is likely that cadherin-mediated adhesion leads to the activation of GEFs, or perhaps the inactivation of GAPs, for Cdc42 and Rac1. RhoA may be regulated by direct interactions with p120^{cas}. When not bound to cadherin, p120^{cas} inhibits activation of RhoA.

Figure 2 Cadherin-mediated adhesion activates Rho family GTPases. The formation of cadherin contacts between cells leads to the activation of Cdc42 and Rac1 (i.e., generation of GTP-bound forms). In the active state, Cdc42 and Rac1 cause alterations in the actin cytoskeleton that lead to the generation of finger-like filopodia and membrane ruffles known as 'lamellipodia', respectively. These events lead to changes in both the ability of cells to adhere to their surroundings and cell migration, and can increase the stability of the cadherin-mediated junctions themselves.

Wnt/ β -Catenin Signaling

In addition to linking the cytoplasmic tails of cadherins to the actin cytoskeleton (see Figure 1), β -catenin is an important component of a signaling pathway involved in both normal development and cancer. Normally, β -catenin molecules not attached to cadherins are degraded in the cytoplasm. When cells are exposed to an extracellular growth factor known as Wnt, β -catenin is protected from degradation and accumulates in the nucleus (Figure 3). There, in association with the T-cell factor/lymphoid enhancer factor (TCF/LEF) family of DNA-binding proteins, β -catenin activates the transcription of genes that stimulate cell proliferation. Thus, the extent to which β -catenin is soaked up by binding to cadherins can potentially modulate the signal generated by activation of the Wnt pathway. High expression levels of E-cadherin can substantially reduce the amount of free β -catenin and lower the cellular response to Wnt. In the absence of Wnt, increased adherens junction formation recruits β -catenin, decreasing the nuclear pool of β -catenin and attenuating β -catenin-mediated transcription. Conversely, disruption of cell-cell adhesion may

Figure 3 Cadherins modulate Wnt/ β -catenin signaling. In addition to its role as a component of adherens junctions, β -catenin (β -ctn) increases the activity of the TCF/LEF transcription factor in the nucleus. The extent to which β -catenin accumulates in the nucleus depends in part upon the level of free β -catenin in the cytoplasm. The amount of free β -catenin is normally low due to its phosphorylation by glycogen synthase kinase-3 (GSK3), binding to adenomatous polyposis coli (APC) and Axin proteins, and subsequent destruction (P indicates the added phosphate group). GSK3 activity is decreased by Dishevelled (Dsh) when the growth factor Wnt binds to its receptor frizzled on the cell surface. Therefore, Wnt can reduce degradation of β -catenin and increase the amount of β -catenin in the nucleus, thereby promoting transcription. By contrast, the formation of cadherin-cadherin junctions, or an increase in the amount of cadherin, can lead to the sequestration of β -catenin due to its interaction with cadherin tails. In this way, cadherins are thought to decrease the amount of nuclear β -catenin and act in opposition to Wnt signals.

Figure 4 Cadherin cross-talk with kinases and phosphatases. Cadherins interact with several growth factor receptors that have intrinsic kinase activity. By this mechanism, cadherins can modulate the signaling cascades triggered by growth factors that lead, for example, to the activation of gene transcription. In addition, activation of receptor kinases can promote the phosphorylation on tyrosine residues of β -catenin (dotted line; P indicates the added phosphate group), its dissociation from cadherin tails, and disassembly of the adherens junction (not shown). Cadherins are also found in a complex with a number of protein phosphatases that can dephosphorylate β -catenin. In this way, cadherins can modulate the reversible phosphorylation of adherens junction components that alter the activity of cadherin itself.

release β -catenin, thereby enhancing transcription. It is noteworthy that mutations of proteins that regulate turnover of β -catenin have been found in several human cancers.

Phosphorylation and Dephosphorylation

The phosphorylation of proteins (i.e., addition of phosphate groups) by kinase enzymes is a common mechanism for regulating numerous cellular processes. Although the cadherins themselves do not have kinase activity, several examples of cross-talk have been observed between cadherins and growth factor receptors that contain intrinsic tyrosine kinases (Figure 4). For example, N-cadherin interacts with the fibroblast growth factor receptor FGFR1 and can boost the phosphorylation cascade triggered by binding of fibroblast growth factor-2 to FGFR1. Analogous interactions may occur between E-cadherin and the epidermal growth factor receptor, as well as VE-cadherin and the vascular endothelial growth factor receptor-2. In this way, cadherins can modulate changes in the survival, proliferation, and motility of cells in response to a variety of growth factors.

Conversely, phosphorylation can modulate inside-out signals to regulate cadherin activity. The association between growth factor receptor tyrosine kinases and cadherins allows growth factors to promote the phosphorylation of several adherens junction proteins (**Figure 4**). A number of non-receptor kinases, including Src, also can phosphorylate junction components. Phosphorylation of β -catenin on tyrosine residues is believed to induce dissociation of β -catenin from cadherins and decrease adherens junction stability. Phosphorylation of the cadherins themselves, and of γ -catenin and p120^{cas}, also modulates adherens junction assembly. In particular, the interaction of p120^{cas} with the cytoplasmic domain of cadherins appears to be an important regulator of cadherin activity, perhaps by attenuating internalization (by endocytosis) or destruction of cadherins. Cadherins are also found in a complex with selected protein phosphatases. These enzymes, which are activated by cadherins, dephosphorylate (i.e., remove phosphate from) β -catenin, allowing reversible regulation of cadherin adhesive capacity (**Figure 4**).

Glossary

Agonist A drug that activates a receptor.

Antagonist A drug that blocks the action of an agonist at a receptor.

Glycosylation The attachment of sugars to a protein.

pA₂ The negative logarithm of the antagonist concentration that causes a twofold shift in the agonist dose–response curve. It is a measure of antagonist affinity.

Calcitonin gene-related peptide (CGRP) and adrenomedullin are abundant, related peptides that share many biological actions. Most prominently, both are very potent vasodilators. CGRP is a neurotransmitter in sensory neurons and adrenomedullin is a hormone that is locally released from tissues including vascular endothelium and smooth muscle. They form a peptide family whose major members are CGRP, calcitonin, adrenomedullin 2/intermedin, and amylin. For some time, there was considerable controversy about the nature of the receptors for this family. It has now been established that they define a new paradigm among G-protein-coupled receptors (GPCRs), in that they are heteromers of a seven-transmembrane-spanning protein that resembles a classical GPCR, the calcitonin receptor (CTR)-like receptor (CLR) and a member of the single-transmembrane-spanning receptor activity-modifying protein (RAMP) family. The CGRP receptor comprises CLR/RAMP1, whereas there are two adrenomedullin receptors: CLR/RAMP2 (AM₁ receptor) and CLR/RAMP3 (AM₂ receptor). RAMPs also interact with other GPCRs.

The Pharmacology of CGRP and Adrenomedullin

The Structure of CGRP and Adrenomedullin

The amino acid sequence identity of CGRP and adrenomedullin (Figure 1) is low but the secondary structure of these peptides is conserved. For both peptides, an amino-terminal ring is important for receptor activation; peptides that lack this structure (CGRP_{8–37} and adrenomedullin_{22–52}) are antagonists.

The Pharmacology of Endogenous CGRP and Adrenomedullin Receptors

CGRP receptor-selective drugs and their pharmacological properties

For CGRP, the most widely used antagonist has been CGRP_{8–37}. This has only limited selectivity. A number of high-affinity nonpeptide antagonists have been developed such as BIBN4096BS and MK0974 (Figure 2), which show marked selectivity for primate over rodent CGRP receptors and have very little affinity for adrenomedullin or other related receptors. It was formerly suggested that CGRP receptors should

be divided into two subtypes: CGRP₁ receptors with a high affinity for CGRP_{8–37} (pA₂ > 7) and CGRP₂ receptors with a lower affinity for this antagonist. It is now clear that only the CGRP₁ receptor is a bone-fide receptor for CGRP and this is now simply called the 'CGRP receptor'. The CGRP₂ receptor is now considered to be a mixture of adrenomedullin (AM₂) and amylin receptors.

The development of nonpeptide CGRP antagonists has been driven by the desire to develop new therapies for migraine. There is good evidence that many of the symptoms of migraine are caused by the release of CGRP by the trigeminal nerve. Both BIBN4096BS (Olcgepant) and MK0974 (Telcagepant) have been evaluated in clinical trials. BIBN4096BS is well tolerated but its use is likely to be limited as it is not orally bioavailable. In phase III clinical trials, MK0974 showed comparable efficacy to the triptan antimigraine drug zolmitriptan but with fewer cardiovascular side effects. However, there is evidence that chronic treatment with MK0974 can cause elevations in serum transaminases, placing some limitations on its use. Nonetheless, the availability of these drugs may open the way to both treatments for migraine and also their evaluation in other conditions where CGRP may play a role, such as hot flushes in postmenopausal women.

Adrenomedullin receptor-selective drugs and their pharmacological properties

The only adrenomedullin antagonist that has been widely used is adrenomedullin_{22–52}. This is not particularly potent (pA₂ ~ 7) and does not antagonize all adrenomedullin-mediated responses. It shows a slight selectivity for AM₁ receptors over the AM₂ receptors but not of a sufficient magnitude to make this a useful agent for defining pharmacology.

Drugs that act against both CGRP and adrenomedullin receptors

Agents that interact solely with CLR, which is common to all the receptors, are likely to block the effects of both peptides. Experimental compounds have been described with these properties; for example, a compound prepared by Merck and also probably SB (+) 273779 (Figure 2). These bind to the receptors with micromolar affinities, around 1000-fold less tightly than the nonpeptide CGRP antagonists.

Figure 1 A comparison of the structure of human CGRP and adrenomedullin_{15–52}. Note the disulfide bond in both peptides, indicated by a bar over the sequences. The first 14 amino acids of adrenomedullin are not required for biological activity and are not shown.

Figure 2 Structures of BIBN4096BS, MK0974, and SB (+) 273779.

The Molecular Structure of CGRP and Adrenomedullin Receptors

CLR and RAMPs

CGRP and adrenomedullin receptors display a very unusual molecular architecture. Both are composed of a common seven-transmembrane-spanning protein called CLR (CL receptor, often shortened to CLR, and previously known as CRLR; **Figure 3**). This is a member of the B-family of GPCRs (related to other receptors, such as those for secretin and calcitonin). Human CLR is 461 amino acids long and has 55.5% sequence identity with the human CTR. By itself, CLR does not function as a receptor for any peptide. However, when associated in a complex with a RAMP, it functions as a high-affinity receptor for either CGRP or adrenomedullin. The RAMPs are a family of three proteins (**Figure 4**), each with an extracellular amino terminus of approximately 100 amino acids, a single transmembrane section, and a very short carboxyl terminus of approximately 10 amino acids. Crystal structures are available for the extracellular domain of RAMP1 (protein database structure 2YX8) and CLRI RAMP1 (protein database structure 3N75).

CLR/RAMP1; the CGRP Receptor

CLR–RAMP1 association is intracellular and this facilitates their transport to the cell surface. There, the complex functions as a CGRP receptor, with a high affinity for CGRP, CGRP_{8–37}, and nonpeptide antagonists such as BIBN4096BS and

MK0974. The complex binds adrenomedullin with an approximately 10-fold lower affinity than CGRP; adrenomedullin 2/intermedin is roughly equipotent with adrenomedullin at this receptor.

Little is known about the mechanism of ligand binding and receptor activation. CGRP can cross-link to both CLR and RAMP1, showing that both components create the peptide-binding site. However, it is not clear whether CGRP has specific contacts with both proteins or whether RAMP1 indirectly contributes to the ligand-binding site by modifying the structure of CLR. It is likely that CGRP makes contacts with both the extracellular domain of CLR/RAMP1 and the membrane–extracellular loop interfaces of CLR. The selectivity of the nonpeptide antagonists is due to a tryptophan residue found at position 74 in RAMP1; this is responsible for their selectivity at primate over rodent CGRP receptors and contributes to their selectivity over adrenomedullin receptors.

CLR/RAMP2 and CLR/RAMP3: The Adrenomedullin Receptors

The heteromers formed by RAMP2 and RAMP3 with CLR produce adrenomedullin receptors. Their formation is very similar to that of the CLR/RAMP1 complex; in the absence of CLR, they are not expressed at the cell surface. It was initially thought that RAMP2 might work by modulating the glycosylation state of CLR. However, it is now thought that adrenomedullin and CGRP both bind to the fully glycosylated form of CLR. As with the CLR/RAMP1 complex, there is little detailed information

Figure 3 The structure of human CLR, showing the postulated seven transmembrane helices. The residues that are likely glycosylation sites on the amino terminus are underlined.

on mechanisms of adrenomedullin binding to either the CLR/RAMP2 or the CLR/RAMP3 complexes, although glutamic acid at position 74 in RAMP3 appears to be important. Both complexes exhibit higher affinity for adrenomedullin than CGRP. The CLR/RAMP2 complex is designated as the AM₁ receptor and the CLR/

RAMP3 complex as the AM₂ receptor. The AM₁ receptor has high affinities for adrenomedullin and adrenomedullin₂₂₋₅₂ but low affinity for CGRP. The AM₂ receptor has high affinity for adrenomedullin and a modest affinity for CGRP. Adrenomedullin 2/intermedin can stimulate both AM₁ and AM₂ receptors.

Cellular Signaling and Receptor Component Protein

The CLR/RAMP complexes are all coupled to the stimulation of adenylate cyclase via the G protein known as G_s . However, as is the case with many related GPCRs, coupling to G_i/G_o and the G_q family of G proteins (leading to changes in ion channel activity and elevation of intracellular calcium) have also been reported. The receptors also associate with β -arrestin, with the potential for activation of further downstream signaling pathways.

A novel protein called receptor component protein (RCP) is reportedly essential for coupling the CGRP and at least the AM_1 receptors to stimulation of G_s . Immunoprecipitation studies suggest that RCP is physically associated with CLR. It has been reported that inhibiting RCP expression disrupts signaling mediated via CGRP and AM_1 receptors. RCP is very widely distributed in cell lines but a broader role has yet to be demonstrated.

Other Receptors that Respond to CGRP and Adrenomedullin

As noted above, amylin receptors can also respond to CGRP. Amylin receptors are complexes between the CTR and RAMPs. The AMY_1 receptor (CTR/RAMP1) has the highest affinity for CGRP, followed by the AMY_3 receptor (CTR/RAMP3). The AMY_2 receptor (CTR/RAMP2) has only a weak affinity for CGRP.

The Distribution and Physiology of CGRP and Adrenomedullin Receptors

The Distribution of Binding Sites for CGRP and Adrenomedullin

CGRP-binding sites are present in both the central nervous system (CNS) and peripheral tissues. In some of the earlier literature, there was confusion due to cross-labeling of what would now be considered amylin receptors. Specific CGRP receptors show the potency order: CGRP > adrenomedullin > amylin. In the rat CNS, the highest densities of CGRP binding are in the nucleus accumbens, caudate putamen, amygdaloid body, pontine nuclei, cerebellum, spinal cord, and inferior olive. In the periphery, CGRP receptors are particularly associated with the cardiovascular system, on blood vessels and in the atria. There are high densities of these receptors in the spleen. However, receptors are also found on nonvascular cells, for example, in the vas deferens and secretory cells in the gastrointestinal tract. In tissues, adrenomedullin receptors show a high level of specificity for adrenomedullin over CGRP or other peptides. Binding in the CNS is highest in the spinal cord, but moderate to low levels are seen in many other brain regions. In the periphery, adrenomedullin binding is closely associated with the cardiovascular system, with very high levels in the heart and lungs.

Distribution of RAMPs and CLR

The most reliable information on the distribution of CLR and RAMPs comes from messenger RNA (mRNA) measurements; antibodies to these proteins are often of uncertain specificity. Generally, there is fair agreement between the distribution of RAMPs and CLR and binding sites for CGRP and adrenomedullin. Often, RAMP2 appears to be more abundant than

RAMP1, with RAMP3 being expressed at the lowest levels. However, there are many exceptions; RAMP1 is the most abundant transcript in the brain and the pancreas and RAMP3 predominates in the liver. There are some anomalies; the nucleus accumbens has strong CGRP binding and RAMP1 expression but little CLR (the binding sites are probably amylin receptors). By contrast, the frontal cortex has very little binding for CGRP, adrenomedullin, or amylin, but has high levels of RAMP expression. RAMPs can associate with other receptors in addition to those for calcitonin and CLR, and so it is not surprising that there should be some variable correlation between the expression of these components.

Changes in Expression of CGRP and Adrenomedullin Receptors

There is good evidence for changes in CGRP and adrenomedullin receptors during various (patho)physiological processes. For example, adjuvant-induced arthritis in rats leads to a decrease in CGRP binding in the spinal cord. Changes in CLR and RAMP expression have also been noted in disease. In a mouse model of sepsis, CLR mRNA and RAMP2 mRNA show large decreases but RAMP3 expression increases in the lung. In a rat model of ischemic heart failure, RAMP2 expression is increased in the ventricles.

The Pathophysiology of CGRP and Adrenomedullin Receptors

Changes in receptor expression suggest that both CGRP and adrenomedullin receptors are of importance during normal physiological processes and in disease. Knockout models for CLR, RAMP2, and adrenomedullin produce similar effects, where homozygotes die *in utero*, showing gross defects in their lymphatic and cardiovascular systems. Heterozygote knockout mice are viable but have reduced fertility; in some, but not all models, there is an increase in blood pressure. Overexpression of RAMP2, while enhancing sensitivity to the vasodilatory effects of adrenomedullin and protecting against vascular hypertension, does not alter resting blood pressure. Thus, adrenomedullin appears to be vital for the development and operation of the cardiovascular and lymphatic systems and failures can lead to infertility but it may not be important for normal control of blood pressure. Overexpression of CLR causes an increase in intraocular pressure, an effect due to enhanced expression of AM_1 receptors in the papillary sphincter muscle. The overall phenotype resembled that of acute angle glaucoma in man.

RAMP3 knockout animals have very different phenotypes to RAMP2 mice; the homozygotes survive to adulthood but gain weight less than controls. Thus, AM_1 and AM_2 receptors have different functions.

Studies on α CGRP-deficient mice have mixed effects, although some workers have noted increased blood pressure, decreased pain sensitivity, and reduced hypersensitivity to antigens in airways. Homozygous RAMP1 knockout animals have elevated blood pressure and an enhanced inflammatory response to lipopolysaccharide. Overexpression of RAMP1 in the trigeminal nerve increases sensitivity to CGRP, as manifested by enhanced plasma extravasation and release of substance P. The data are consistent with roles for CGRP in the

cardiovascular system and also as an inflammatory mediator (with both pro- and anti-inflammatory actions, depending on the cellular context), involved in pain perception and the activation of cells of the immune system.

In summary, the evidence from genetic manipulation of CGRP and adrenomedullin receptor components is that this changes receptor sensitivity and can give phenotypes consistent with the involvement of these receptors in human disease. Further, changes in the receptors are observed in diseases and disease models. Thus, there are grounds for thinking that stimulation or inhibition of CGRP and adrenomedullin receptors may be important in both chronic and acute conditions involving, for example, angiogenesis, lymphangiogenesis, and inflammation.

Glossary

Affinity The strength with which a chemical messenger binds to its receptor.

Calcitonin (CT) A small peptide hormone and a potent inhibitor of bone resorption.

Downregulation A decrease in receptor number resulting from prolonged exposure to high concentration of the message.

G proteins A family of plasma membrane regulatory proteins that many activated receptors interact with and alter.

Osteoclast A large multinucleated bone cell that can destroy bone.

Phospholipase C Enzyme that catalyzes the breakdown of a plasma membrane phospholipid known as

phosphatidyl-inositol bisphosphate (PIP₂) to inositol triphosphate (IP₃) and diacylglycerol (DAG).

Protein kinases Enzymes that phosphorylate other proteins by transferring to them a phosphate group from adenosine triphosphate. Introduction of a phosphate group alters the activity of the protein, often itself an enzyme.

Receptor modulation A molecular mechanism, whereby cells/tissues could change their responsiveness to different peptides.

Receptor-activity-modifying proteins (RAMPs) Single transmembrane-domain proteins that alter the phenotype of the calcitonin receptor, calcitonin receptor-like receptor and other G-protein-coupled receptors.

Second messengers Substances that serve as the relay from the plasma membrane to the biochemical machinery inside the cell.

Calcitonin Peptide Family

This article is dedicated to the memory of Professor Iain MacIntyre, who was the senior author of CT receptor chapter of the 1st edition of the *Encyclopedia of Biological Chemistry* in 2004. The calcitonin peptide family comprises seven known members (calcitonin (CT), amylin (AMY), two calcitonin gene-related peptides (CGRP α and CGRP β), adrenomedullin (AM), intermedin (IMD), and calcitonin receptor-stimulating peptide (CRSP)). These peptides display a weak homology at the primary structure but are similar in their secondary structure. They share a ring structure, formed by a disulfide bridge at or near the N-terminus, and have C-terminal amides, which are essential for full biological activity (Figure 1). They have some overlapping biological effects due to cross-reactivity at each other's receptors.

Calcitonin

Calcitonin (CT) is a small peptide hormone secreted mainly by special type of cells within the thyroid gland in mammals, called C cells. These cells originate from the neural crest and then migrate during embryonic development to be localized mainly in the thyroid gland in mammals. However, in submammalian vertebrates these cells remain as a separate gland, termed the ultimobranchial body. CT is a potent inhibitor of bone resorption, acting via receptor-mediated inhibition of osteoclast function. In addition to its effect on bone, CT has a wide range of biological activities, including analgesic effect, suppression

of gastric acid secretion, and appetite. On the kidney, CT enhances the excretion of sodium, calcium, and phosphate.

CT was first identified as a calcium-lowering factor in 1961. The calcium-lowering effect of CT is mainly due to direct inhibition of osteoclast activity, and, to a lesser extent, is due to increasing calcium excretion by the kidney. The potency of CTs from different species greatly varies, with submammalian CTs (e.g., salmon CT and eel CT) being the most potent. Because of its potent inhibitory effect on osteoclastic bone resorption, CT is used in the treatment of conditions associated with increased bone resorption such as Paget's disease of bone, osteoporosis, and hypercalcemia of malignancy. Medullary thyroid carcinoma is a tumor of the C cells of the thyroid gland that produce and secrete abnormally large amounts of CT. Measurement levels of CT in the blood of these patients is useful in the diagnosis and monitoring of this condition.

Calcitonin Gene-Related Peptides

Calcitonin gene-related peptides (CGRPs) are highly conserved neuropeptides among various species. There are two forms, CGRP α and CGRP β , which differ in only three amino acids in humans and in one amino acid in rats. Each peptide is the product of a separate gene. In human, both genes are localized on the short arm of chromosome 11. CGRP α is the product of the calcitonin gene, referred to as Calc I or CT/CGRP α gene. One feature of this gene is that alternative splicing of the primary RNA transcript leads to the differential of either CT mRNA in the thyroid C cells or alternatively to CGRP α messenger RNA (mRNA) in neural tissues. CGRP α is abundantly

Figure 1 The CT peptide family. The peptides share a six-/seven-amino-acid ring structure, formed by a disulphide bridge at or close to the N terminus. The peptides also have C-terminal amides, which are essential for full biological activity. Adapted from Girgis SI and MacIntyre I (2002), Calcitonin Gene-related Peptide (CGRP). In: Creghton TE (ed.) *Encyclopedia of Molecular Medicine*, 5 vols. New York, NY: Wiley, with permission from John Wiley and Sons.

and widely distributed neuropeptide throughout the central and peripheral nervous systems. It is present most abundantly in sensory neurons, where it is mostly co-localized with substance P (SP). It is found in motoneurons and neurons of the autonomic nervous system. It is also abundant in the posterior horn of the spinal cord suggesting a role in the transmission of sensory impulses. CGRP-containing nerve fibers are widely distributed to most organ system, and are particularly abundant around arteries. By contrast, CGRP β is localized primarily in the gut, in sites including the enteric nerves and the pituitary gland.

CGRP is one of the most potent vasodilator substances identified to date, with a potency ~ 10 -fold greater than prostaglandin and 100–1000 times greater than other classic vasodilators. Both forms of CGRP have similarly potent biological activity in terms of vasodilator activity.

The distribution of CGRP-containing nerves throughout the vascular system and its potent vasodilatory effects suggests an important role for CGRP in the modulation of vascular tone and in the regulation of regional blood flow. Further evidence of the physiological importance of CGRP α came from gene-knockout mice. Mice deficient in CGRP α demonstrated elevated peripheral vascular resistance and high blood pressure caused by increased peripheral sympathetic activity.

Amylin

AMY is a peptide hormone that is produced principally by β cells of the pancreas (cells that secrete insulin). It is co-localized with insulin within the same secretory granules, and co-secreted with insulin in response to a high blood glucose, for example, after a meal. AMY is also found in much smaller quantities in the gut. It opposes the metabolic actions of insulin in skeletal muscle. AMY is also a potent inhibitor of gastric emptying and of food intake. In the kidney, AMY enhances renin activity. It appeared to have a role in the development of the kidney. Although less potent than CT, AMY also inhibits the activity and formation of osteoclasts. AMY-deficient mice (by deletion of the gene encoding AMY) develop a low bone mass phenotype mimicking osteoporosis, which is solely due to an increase in bone resorption. AMY is now considered a crucial physiological inhibitor of bone resorption.

Adrenomedullin

This regulatory peptide was first isolated from human pheochromocytoma (a tumor of the adrenal medulla) in 1993. Unlike CGRP, AM is produced primarily by non-neural tissues especially vascular endothelial and smooth muscle cells. It is widely expressed mainly in areas where microvascular vessels exist (e.g., lungs, brain, kidneys, and bone). It is also found in the adrenal medullae and in a variety of cells including fibroblasts and macrophages.

As CGRP, AM has multiple biological effects including potent vasodilation. It acts directly on the renal, pulmonary, cerebral, mesenteric, and systemic circulation including the vascular supply of the skeleton. In the kidney, AM enhances the excretion of sodium. AM also acts as a local regulatory factor that can influence cell growth and development. Studies of gene-knockout mice revealed the physiological importance of AM. Deletion of the AM gene proved to be lethal beyond mid-gestation due to defective development of blood vessels. AM $\pm$ heterozygous mice showed high blood pressure and susceptibility to tissue injury. Thus, AM is essential for normal embryonic development, regulation of blood pressure, and tissue protection against injury.

Intermedin or AM2

This peptide is predominantly expressed in the hypothalamus where it is co-localized with arginine vasopressin, in the pituitary gland (in the intermediate lobe, hence the name intermedin), and in the kidney. Its distribution is consistent with a physiological role in the central regulation of thirst, fluid, and electrolyte balance. IMD is a potent systemic and pulmonary vasodilator. It influences regional blood flow and enhances cardiac contractility.

Calcitonin Receptor-Stimulating Peptide 1

CRSP-1 is expressed and secreted in the hypothalamus, mid-brain, and pituitary. It has a high amino acid sequence similarity with CGRP and participates in physiological regulation in peripheral tissue and central nervous system (CNS). It inhibits food intake, pain sensation, and locomotive activity. It has been identified in mammals but not specifically in humans.

Receptors for the Calcitonin Peptide Family

Receptors for the whole CT peptide family can be reconstituted by two GPCRs (the CTR and the calcitonin receptor-like receptor CLR) and three RAMPs.

The CT Receptor

Distribution

CTRs are widely distributed. They are particularly numerous in osteoclasts, where there are approximately 1.3 million receptors per cell. They are found in smaller amounts in the CNS, in areas involved in the control of appetite, pain perception, and of lactation, for example, the hypothalamus and the pituitary. CTRs are also found in peripheral tissues, for example, in cells of the distal nephron of the kidney, testes, placenta, lung, prostate, and lymphocytes. Receptors for CT have been identified in some human cancer cells, including those of lung, breast, bone, and prostate.

Protein structure

The CTR was initially cloned from a pig kidney cell line in 1991. Analysis of the predicted 482 amino acid sequences demonstrated seven hydrophobic regions that could generate transmembrane (TM)-spanning domains. The CTR is a member of a subset of the G-protein-coupled receptors (GPCRs) family termed GPCR_β. Members of this family typically recognize regulatory peptides, including parathyroid hormone (PTH/PTH-rp), vasoactive intestinal polypeptide (VIP), glucagons, growth hormone-releasing hormone, gastrin inhibitory polypeptide, and secretin. This family of receptors is characterized by seven TM segments connected by three extracellular and three intracellular loops (Figure 2). They all have an extracellular amino (N)-terminal sequence and an intra-cellular carboxy (C)-terminal sequence. The extended extracellular N-terminal region contains multiple potential glycosylation sites and conserved cysteine

Figure 2 Schematic representation of the porcine CTR. Seven transmembrane regions span the cell membrane, and are connected by three extracellular and three intracellular loops. The amino-terminal extracellular loop contains three glycosylation sites (indicated by stars) and is involved with CT recognition and binding. The intracellular domain is involved with G-protein coupling. Reproduced from Girgis SI, Moraldi-Bidhendi N, Mancini L, and MacIntyre I (2004) *Encyclopedia of Biological Chemistry*, 1st edn. London: Elsevier, with permission from Elsevier.

residues. Glycosylation is important for recognition and high-affinity binding of CT. While the TM domain sequences are conserved (40–60% identical), the N-terminal domains are generally less than 25% identical. The N-terminal domain fulfills the role for ligand binding and receptor specificity.

Multiple forms

The human CTR gene is localized to chromosome 7. The CTR gene has a complex structural organization with several CTR protein isoforms derived from alternative splicing of transcripts from a single gene. These isoforms are functionally distinct in terms of ligand-binding specificity, signal transduction pathway utilization, and tissue distribution. In humans, at least five splice variants have been found, whereas only two splice variants have been identified in rodents (C1a and C1b), which differ, by the presence or absence of an additional 37 amino acids, in the second extracellular domain. The C1a is more widely distributed and is the predominant isoform found in osteoclasts. C1b isoform is primarily localized in the CNS.

Signaling

The CTR is coupled to multiple signal pathways through interaction with different members of the heterotrimeric G-protein family. These are a family of plasma membrane regulatory proteins that interact with and alter activated receptors. The main signal pathways are as follows.

The adenylate cyclase/cAMP/protein kinase A. The binding of CT to its receptor induces conformational change in the receptor that allows it to bind to an adjacent membrane G-protein, known as G_s (the subscript s denotes stimulation). The binding causes the G_s protein to activate the membrane enzyme called 'adenylate cyclase'. The activated adenylate cyclase, whose catalytic site is on the cytosolic site of the plasma membrane, then catalyzes the conversion of cytosolic ATP to cyclic 3', 5' adenosine monophosphate (cAMP). Cyclic AMP can diffuse throughout the cell to trigger the sequence of events leading to the cell's ultimate response to CT.

The phosphoinositol-dependent phospholipase C (PLC) pathway. The pathway which results in both an increase in intracellular Ca²⁺ and protein kinase C (PKC) activation via G_q protein. Both cAMP and intracellular Ca²⁺ are important second messengers for mediating the actions of CT on the osteoclast.

While adenylate cyclase, PLC, and PLD are established effectors for CTR, recently CTR-mediated activation of the mitogen-activated protein kinase (MAPK) pathway has been described. MAPKs are a group of serine/threonine protein kinases that are activated by several distinct classes of cell surface receptors, including G-protein coupled receptors and tyrosine kinases.

Regulation

Regulation of the level or affinity of cell-surface receptors is a key component in the response to either endogenous or administered agents. The CTR is subject to both homologous (CT-induced) and heterologous regulation. Although CT effectively inhibits osteoclast-mediated bone resorption after acute administration, continuous exposure to CT results in a loss of responsiveness due to receptor downregulation. Continuous treatment of osteoclast-like cells with CT results in the decrease in steady state levels of CTR mRNA and downregulation of CTR binding. It is also known that glucocorticoids stimulate CTR expression.

Figure 3 The role of RAMPs 1 and 2 and CLR (CRLR) in generating CGRP or ADM receptors. Adapted from McLatchie LM, Fraser NJ, Main MJ, et al. (1998) RAMPs regulate the transport and ligand specificity of the calcitonin receptor-like receptor. *Nature (London)* 393: 333–339, with permission from Nature Publishing Group.

CTR-Like Receptor

The rat CLR was first identified in 1993. The receptor has a significant sequence homology (55%) with the corresponding CTR and share similarities in general structure and length (belongs to the GPCR_β family of receptors). Historically, this protein has been abbreviated as CRLR; however, it will be referred to in this article as CLR. Initially, it was considered an ‘orphan’ receptor. The important breakthrough came in 1998 when an expression cloning approach demonstrated that CLR required a single-cell membrane protein called receptor activity modifying protein, RAMP1, to function as a CGRP receptor (Figure 3). RAMP2 and RAMP3 enable the same CLR to behave as an AM receptor (Table 1). CLR alone does not bind with high affinity to any of the members of the CT peptide family.

Immunohistochemical analysis revealed the presence of the CRL in the endothelium of all blood vessels including large and small arteries, veins, capillaries, in heart muscle cells, and the endocardium. The CLR is ubiquitously expressed in a variety of tissues, being most prevalent in the brain, and in high densities in the pulmonary and cardiovascular system (especially in blood vessels). It is also expressed in the adrenal and pituitary glands, in the pancreas in the islets of Langerhans, kidney, and bone.

Receptor-Activity-Modifying Proteins

The RAMP family of proteins comprises three members: RAMP1, RAMP2, and RAMP3. They belong to the family of type I single trans-membrane proteins. They have a large

Table 1 Nomenclature of receptors resulting from the association of individual RAMPs with either CTR or CLR

Molecular units	Receptor name
CTR + RAMP1	AMY1
CTR + RAMP2	AMY2
CTR + RAMP3	AMY3
CLR + RAMP1	CGRP
CLR + RAMP2	AM1
CLR + RAMP3	AM2

Amylin (AMY) receptors are formed by the association of the calcitonin receptor (CTR) with one of the three receptor-activity modifying proteins (RAMPs), whereas CGRP and adrenomedullin (AM) receptors are formed by the association of the calcitonin receptor-like receptor (CLR) with one of the RAMPs. From Poyner DR, Sexton PM, Marshall I, et al. (2002) International Union of Pharmacology. XXXII. The mammalian calcitonin gene-related peptides, adrenomedullin, amylin, and calcitonin receptors. *Pharmacological Reviews* 54: 233–246; Hay DL, Poyner DR, and Quirion R (2008) International Union of Pharmacology. LXIX. Status of calcitonin gene-related peptide subtype 2 receptor. *Pharmacological Reviews* 60: 143–145.

extracellular amino terminal domain, a single TM spanning domain and a short, ~10 amino acids, cytosolic domain. The three RAMPs share a similar basic structure but have only about 30% identity in the amino acid sequence. One important function of RAMPs is to control the glycosylation of the CLR and thus its transportation to the cell membrane. For example, RAMP1 acts to modify the glycosylation of CLR, enhance the transport of the receptor protein to the cell surface and potentially contribute to the receptor phenotype. RAMP1-transported CLR is a CGRP receptor. RAMP2 and 3 also enhance the transport of CLR to the cell surface, but do not

alter the pattern of glycosylation of the receptor. RAMP2 or 3-CLR is an ADM receptor.

RAMP1 is widely expressed in the brain, spinal cord, gastrointestinal tract, adrenal gland, perivascular nerve, and smooth muscles of the arteries. RAMP2 is found in macrovascular and microvascular endothelial cells, vascular smooth muscle, and cardiomyocytes. RAMP3 is less extensively distributed: high levels are found in kidney, lung, spleen, and thymus.

Glossary

Actin A eukaryotic protein that has the capability to form thin helical filaments.

Alternative splicing Alternate usage of particular exons to create isoforms of a given protein.

Amphipathic proteins Proteins composed of helices containing both hydrophobic and hydrophilic amino acid residues.

Apoptosis Apoptosis (or programmed cell death) is derived from a Greek word describing the shedding of leaves from trees. During apoptosis, the cell responds to specific physiological or developmental signals undergoing a regulated, well-programmed series of events which will lead to its death and its removal from the organism.

Cytoskeleton Complement of actin filaments, microtubules, and intermediate filaments forming a network in the cytoplasm.

EF-hand proteins Term coined by R.H. Kretsinger to describe the helix-loop-helix calcium-binding domains of specific proteins. The highly conserved motif (first described on the basis of the crystal structure of parvalbumin containing six helices, A–F) in which certain amino acids are invariant consists of two helices enclosing the Ca²⁺-binding

loop. As a model, the forefinger and the thumb of the right hand can resemble the two helices (e.g., E and F of the second Ca²⁺-binding domain of parvalbumin) and the bent midfinger the enclosed loop, hence the EF-hand.

Exon Segments of a eukaryotic gene preserved in the mature messenger RNA.

Intron Segments of a gene transcribed into the precursor RNA but excised by RNA splicing before the mature RNA is exported from the nucleus into the cytoplasm.

Posttranslational modification Enzymatic modification such as acetylation, phosphorylation, myristoylation, or ubiquitination of proteins regulate their activity, topology, or degradation.

Second messenger Intracellular small molecules (e.g., cyclic nucleotides or inositol polyphosphates) or ions such as Ca²⁺ or gases such as NO, indispensable for the transduction of signals converting extracellular stimuli – e.g., raised by hormones (=primary messengers) – into intracellular responses.

Splicing Removal of introns from the precursor messenger RNA and joining of exons in mature messenger RNA; positions of boundaries between introns and exons are often conserved in homologous proteins of different species.

Calcium is one of the most common elements on the Earth, and it is the fifth most abundant element of the human body. Inside cells, calcium is a very versatile second messenger involved in the regulation of a variety of different cellular processes. This pivotal role of calcium is made possible due to the binding of Ca²⁺ to a great variety of different calcium-binding proteins. Next to the well-studied family of the so-called EF-hand containing proteins, a number of other calcium-binding proteins became known in recent years. These proteins are composed of a number of repeat units containing a variety of different Ca²⁺-binding sites. The families of annexins, gelsolins, and C₂-domain containing proteins described in this article bind to different membranous or cytoskeletal structures in a Ca²⁺-dependent manner, and are involved in a number of different cellular functions.

Annexins

The family of intracellular Ca²⁺-binding proteins called ‘annexins’ are soluble, amphipathic proteins that bind to membranes containing negatively charged phospholipids in a Ca²⁺-dependent manner. They are called annexins since they bring or hold together different cellular structures, in particular membranes. The close to 200 different annexin proteins

known to date are widespread in the animal and plant kingdoms, and have been claimed to be involved in a variety of cellular functions such as interaction with the cytoskeleton, membrane fusion, anticoagulation, signal transduction, or phospholipase inhibition. The primary structure of the annexins contains four or eight (annexin A6) conserved repeat units of ~75 amino acids in length. This protein core consists of five alpha helices, which are separated by intervening sequences of variable length. These repeat units probably originated from gene duplications, a view which is corroborated by the evolutionary conservation of the intron–exon boundary positions. Most annexins containing four repeat units are comprised of 12–15 exons resulting in a quite variable amino-terminal part of the different annexins. Most alternative splicing sites have been located within exons encoding the variable amino-terminal parts of annexins. Since these parts are also the locations containing motifs for binding partners or for post-translational modifications, alternative splicing may contribute to the regulation of annexin function.

After the first determination of an annexin crystal structure (annexin A5) by Huber and his co-workers, a number of additional annexin structures from different sources (including those from lower eukaryotes and plants) have been reported. From these structures, it can be concluded that the conserved repeat units are packed into an α -helical disk, as first described for

annexin A5, which is almost entirely α -helical. It consists of five α -helices bundled into a right-handed super-helix. On the basis of this structure it was proposed that annexin A5 functions as a calcium channel, and some experiments using an *in vitro* reconstituted system seem to support a voltage-gated mechanism. This property is connected with the structure of the annexin core, which is shared by most annexins. Meanwhile, for most annexins a Ca^{2+} channel activity has been demonstrated in artificial bilayer systems, but never *in vivo*; therefore, the physiological relevance of these observations is questionable.

In contrast to the EF-hand containing Ca^{2+} -binding proteins, the ligands coordinating calcium in the annexins are not adjacent in sequence. Several calcium-binding sites seem to exist in annexins, two invariably in repeats II and IV, one in either repeat I or III, but annexins may contain as many as 10–12 Ca^{2+} -binding sites along the membrane-binding surface of the protein. The sites with the highest Ca^{2+} affinity are structurally related to the Ca^{2+} - and phospholipid-binding site of phospholipase A₂. The calcium ion is heptacoordinated with ligands organized in a pentagonal bipyramidal arrangement with ligating oxygens provided mainly from peptide carbonyls and water molecules, together with a single side-chain oxygen from a distant part of the sequence. Replacement of this latter capping residue, which is usually acidic, with alanine precludes Ca^{2+} binding at the site. Once bound to membranes, many annexins oligomerize to form highly ordered two-dimensional arrays that have been shown to strongly influence *in vitro* membrane properties, for example, increased rigidity.

An interesting feature is the role of Trp185 in the Ca^{2+} -binding site of repeat III of annexin A5 (see Figure 1). As suggested by Seaton and others, a Ca^{2+} -dependent exposure of Trp185, which is buried within the protein core in the absence of calcium, may facilitate the interaction between annexin A5 and the phospholipid bilayer. This view has been supported by fluorescence data and by mutagenesis experiments in which replacement of Trp185 by alanine decreased the annexin A5 membrane-binding affinity.

Annexins have long been known as targets for post-translational modifications. In fact, annexin A2 was originally isolated as a major substrate of the *src*-encoded protein kinase, and annexin A1 was long known to be phosphorylated by the tyrosine kinase activity of the epidermal growth factor (EGF) receptor, suggesting that annexins A1 and A2 could be used as

coupling factors between growth factor receptors and their cellular targets, since these phosphorylations alter the Ca^{2+} -dependent binding of annexin A1 and A2 to membranes. In addition to the phosphorylation by different tyrosine kinases, also serine/threonine kinases have been identified to phosphorylate annexins. As a result, annexin phosphorylation often leads to an altered susceptibility toward proteolysis. On the other hand, phosphorylation of annexin A2 by different kinases interferes with its ability to form stable heterotetrameric complexes with p11, a member of the calcium binding S100 family (S100A10), since these phosphorylation sites are located – like in the other annexins – within the variable amino-terminal domain, which comprises also binding motifs to interact with other proteins. S100A10 itself is not able to bind Ca^{2+} due to mutations critical for Ca^{2+} binding. Based on the crystal structure solved by Rety et al., it was suggested that S100A10 is in a kind of Ca^{2+} -activated conformation even in the absence of Ca^{2+} which enables S100A10 to form a heterotetrameric complex with annexin A2 as reported by Rety et al. who also solved the structure of the heterotetrameric complex between S100A10 and the N-terminal peptide of annexin A2 representing the S100A10 binding site. The Ca^{2+} sensitivity of the annexin A2/S100A10 complex in phospholipid binding is increased by three orders of magnitude as compared to free annexin A2. Next to the interaction between annexin A2 and S100A10 (p11), two other complexes between an annexin and an EF-hand containing protein of the S100 family may exist, that is, interactions between annexin A11 and S100A6 and annexin A1 and S100A11, respectively, but in contrast to annexin A2/S100A10 the existence of the latter complexes *in vivo* has not been described to date.

In spite of extended studies in many laboratories over the years, the precise function of individual annexins is not yet understood. The accumulated data suggest that due to the many ways that annexins interact with different membranes in a Ca^{2+} -dependent manner, annexins may participate in Ca^{2+} signaling as effectors, mediators, or even as regulators, but to clarify their biological activities unambiguously, this has to await further experiments. However, *in vivo* experiments from knockout and transgenic mice are beginning to shed some light on annexin function.

A number of annexinopathies have been described in the literature, for example, connected with the anti-phospholipid syndrome, diabetes, or with different forms of heart failures. A direct connection between an annexin anomaly and a human disease seems to occur in acute promyelocytic leukemia (APL), a subset of acute myelocytic leukemia (AML). It is characteristic for cells from patients with APL that annexin A2 is upregulated. These cells can be characterized by a disruption of the retinoic acid receptor alpha gene due to a fusion with the PML tumor-suppressor gene product followed by a translocation which causes a fibrinolytic phenotype. It is interesting to note that this phenotype can be induced in cells overexpressing annexin A2 and inhibited by annexin A2-specific antibodies in promyelocytic cells showing the specific translocation mentioned before. These observations indicate that dysregulated overexpression of annexin A2 may cause the fibrinolytic complications of APL. In another recent study, annexin A1 was shown to regulate transforming growth factor (TGF)- β signaling to promote the formation of metastatic cells in basal-like breast

Figure 1 Superposition of α -carbon backbones of annexin A5 in the Ca^{2+} -free and the Ca^{2+} -bound form. Domains 1, 2, and 4 are light green, both in the Ca^{2+} -free and in the Ca^{2+} -bound form. Domain 3 is shown in magenta (Ca^{2+} free, trp185 buried) and in blue (Ca^{2+} bound, trp185 exposed). cancer (BLBC). In a proteomic analysis, De Graauw et al. in 2010 identified annexin A1 as a possible candidate to regulate a cell morphology switch to change epithelial cells to a more migratory phenotype. In a detailed study, the authors provided evidence that high expression of annexin A1 is associated with the BLBC phenotype of breast cancer, whereas depletion of annexin A1 prevented the migratory phenotype associated with decreased TGF- β signaling. Using annexin A1 as a marker in tissue microarrays, BLBC patients could be unambiguously discriminated from other breast cancer patients indicating that annexin A1 is functionally involved in BLBC progression and metastasis formation.

Gelsolin

Gelsolin belongs to the superfamily of actin-binding proteins (ABPs) expressed in all eukaryotes. It is a multifunctional protein, binding actin in a Ca²⁺-dependent manner, and is composed of up to six repeats of 120–150 amino acids. To the gelsolin family belong proteins such as villin, adseverin, CapG, filil, and others. Villin, for example, is a six gelsolin-domain ABP regulating actin assembly in microvilli, whereas CapG is a smaller, three-domain gelsolin analog that responds to Ca²⁺ and phosphatidylinositol-(4,5)-diphosphate under conditions where gelsolin is ineffective.

Recently, the crystal structure of the C-terminal region of adseverin, containing six domains (A1–A6) homologous to the six gelsolin domains (G1–G6), was solved by the group of Robinson. Biochemical studies have indicated that gelsolin contacts actin through two sites on G4 and G6 whereas adseverin interacts with actin by using a site on A5. By a detailed comparison between the Ca²⁺-bound structures of G4–G6 from gelsolin with A4–A6 from adseverin, a high conservation in calcium and actin binding could be detected which is not surprising due to the 60% sequence identity between the two proteins. Therefore, these structural data indicate that adseverin and gelsolin respond to calcium and bind actin monomers in a similar manner.

Alternative transcription initiation and selective RNA processing produces two isoforms of gelsolin from the same gene. One isoform of 80 kDa is located intracellular, whereas the other extracellular, slightly larger (83-kDa) protein is derived by alternative splicing, which results in a short amino-terminal elongation of the protein. The intracellular gelsolin is involved in cell motility regulating actin function, whereas extracellular gelsolin can act as an actin-scavenging system to prevent the polymerization of actin released after cell death.

Gelsolin consists of six repeat units (G1–6). The units are organized in two clusters of similar architecture, and are connected by a flexible linker of ~50 amino acids that may be cleaved by caspase-3, thereby cleaving the actin-binding domain of gelsolin from its calcium-binding domain. Caspase-3 cleavage and separation of subdomains of gelsolin coincide with plasma membrane blebbing, one of the characteristics of apoptosis. Apoptosis could also be induced by the overexpression of the amino-terminal half of gelsolin, whereas neutrophils of gelsolin-null mice have a delayed onset of apoptosis.

The structure of gelsolin in the absence of Ca²⁺ has been determined at 2.5 Å resolution by Robinson and his

co-workers (Figure 2). The amino-terminal half can bind to two actin monomers independent of calcium, whereas the carboxy-terminal half binds a single actin in a Ca²⁺-dependent manner.

A detailed mechanism for the regulation of gelsolin activity by Ca²⁺ has recently been proposed. This was made possible by comparing the Ca²⁺-free structure of nonactive gelsolin (Figure 2) with the recently solved structure of the active form of Ca²⁺-bound gelsolin complexed to actin (see Figure 3). In this latter structure consisting of the C-terminal half of gelsolin, that is, G4–6, bound to monomeric actin, two classes of Ca²⁺-binding sites have been identified: type-1 sites bind calcium in a coordination sphere shared by actin and gelsolin, whereas type-2 sites are identified only in gelsolin, that is, located within G5 and G6. Due to conservation of the ligating residues within all gelsolin repeats, type-2 Ca²⁺-binding sites should exist in all six domains of gelsolin. In total, gelsolin should be able to bind eight calcium ions in the active gelsolin–actin complex, that is, two in type-1 sites and six in type 2. The latter are proposed to facilitate structural rearrangements within gelsolin as part of the activation and actin-binding process.

In the absence of Ca²⁺, the six repeat units of gelsolin provide a very compact globular structure, thus blocking the actin-binding helices of the appropriate subdomains. Therefore, in a first step, this compact globular arrangement of the six subdomains has to be opened up. As suggested by H. Choe and co-workers in 2002, binding of Ca²⁺ first to G6 should induce a conformational rearrangement in which G6 is flipped over G5 to tear apart the continuous β -sheet core of G4 and G6, thereby unmasking the actin-binding site on G4, and hence permit binding to actin strands (see Figure 3). Similar events should also occur in the N-terminal half of gelsolin, that is, Ca²⁺ binding to G3, flipping over G2 to open up the actin-binding site of G1. Finally, to tighten up the gelsolin–actin complex, Ca²⁺ binds to the two type-1 sites shared between actin and gelsolin, which might explain the very high affinity of gelsolin to actin (K_d 50 nM).

Figure 2 A ribbon diagram of the structure of gelsolin in the absence of calcium. The following color code for the different segments (G1–6) has been used: G1 (containing the amino terminus), red; G2, light green; G3, yellow; G4, magenta; G5, dark green; and G6 (containing the carboxy terminus), gold. Reproduced from Burtnick LD, Koepf EK, Grimes J, et al. (1997) The crystal structure of plasma gelsolin: Implications for actin severing, capping, and nucleation. *Cell* 90: 661–670, with permission from Elsevier.

Figure 3 Ribbon diagram of gelsolin domains G4–G6 demonstrating the influence of binding Ca^{2+} and actin (shown in cyan) on the conformational changes of the protein. The same color code as in [Figure 2](#) is used for domains G4–G6. The left-hand panel shows G4–G6 in a Ca^{2+} -free conformation (see [Figure 2](#)), whereas the right-hand panel depicts the actin and Ca^{2+} -bound form of G4–6. Reproduced from Choe H, Burtnick LD, Mejillano M, et al. (2002) The calcium activation of gelsolin: Insights from the 3 Å structure of the G4–G6/actin complex. *Journal of Molecular Biology* 324: 691–702, with permission from Elsevier.

In a recent study, Nag et al. in 2009 made the interesting observation that G2 and G6 seem to be cooperative with respect to Ca^{2+} binding to gelsolin, and thus be responsible for the exposure of the actin-binding site on G2. By a detailed analysis it could be shown that due to mutations of the two conserved Ca^{2+} -coordinating residues Asp and Glu to Asn and Gln in G2 a destabilization of the gelsolin structure could be observed, resulting in a sustained exposure of a protease cleavage site. In this respect it is of interest that the hereditary disease known as familial amyloidosis Finnish-type (FAF) is based on a single mutation within the Ca^{2+} -binding site in G2 of gelsolin in which Asp187 is mutated to Asn or Tyr, thereby destabilizing the gelsolin structure through loss of Ca^{2+} coordination. This makes the protein susceptible to protease cleavage in the Golgi compartment.

Gelsolin-null mice show normal embryonic development, but suffer subtle changes. This suggests the need of gelsolin for cell motility during processes such as hemostasis leading to reduced platelet function, inflammation leading to delayed neutrophil migration, or during wound healing, which would lead to reduced movement of fibroblasts. In this context, it is interesting to note that it was demonstrated that during development of zebrafish embryos, gelsolin is required for dorso-ventral patterning. Inhibition of gelsolin expression that starts to be expressed already at the two-cell stage resulted in ventralized phenotypes, some of which lacked brain or eyes. These phenotypes could be rescued by injecting zebrafish gelsolin messenger RNA (mRNA) or even by injecting human gelsolin protein. These data indicate that gelsolin may have at least two separate functions: a structural role for the cytoskeletal/cell motility apparatus and a regulatory role during development.

C₂-Domain Proteins

Interaction of proteins, intracellularly or extracellularly, often occurs via different binding modules or domains such as SH2, SH3, WW, PDZ, or C₂-domains. These modules are formed by folding domains consisting of 100–150 residues with different binding properties, that is, SH2-domains interact with phosphotyrosine-containing sequences, SH3- and WW-domains with proline-rich sequences, PDZ-domains with C-terminal

sequences to link multiprotein complexes to the cytoskeleton, and C₂-domains with phospholipids, some in a Ca^{2+} -dependent, some in a Ca^{2+} -independent manner. C₂-domains consist of about 120–130 amino acid residues. They were first identified in protein kinase C. More than 100 C₂-domain containing proteins can now be identified in current data banks.

Most proteins containing C₂-domains either are linked to signal transduction pathways or are involved in membrane traffic. The former proteins either generate lipid second messengers (e.g., phospholipase A2, phospholipase C, or phosphatidylinositol-3-kinase), phosphorylate proteins (e.g., protein kinase C), or ligate ubiquitin (e.g., Nedd4). Those proteins involved in membrane traffic include, for instance, the Rab-binding proteins rabphilin and RIM, which are involved in regulating the exocytosis of secretory vesicles. However, the best-characterized protein of this category is synaptotagmin, which will be discussed in more detail.

Synaptotagmin I is a transmembrane protein belonging to a family of more than 10 members which contain two C₂-domains, C₂A and C₂B, comprising most of the cytoplasmic region of synaptotagmins. The C₂-domains contain Ca^{2+} -binding domains of non-EF-hand character. Synaptotagmin I is found in synaptic vesicles, and is believed to act as the major Ca^{2+} -sensor of exocytosis and neurotransmitter release. Important in this respect is the Ca^{2+} -dependent binding of synaptotagmin to syntaxin, a member of the SNARE family of membrane proteins, involved in vesicle transport mechanisms.

C₂-domains have been suggested to be responsible for binding to membranes in response to Ca^{2+} . Sudhof and his co-workers determined the first structure of a C₂-domain, the C₂A-domain of synaptotagmin I (see [Figure 4](#)). The C₂-domain consists of a β -sandwich of two four-stranded β -sheets ([Figure 4\(a\)](#)). The eight β -strands are connected by three loops at the top that bind Ca^{2+} in the form of a cluster, primarily through oxygen of aspartate side chains serving as bidentate ligands, and by four loops at the bottom lacking Ca^{2+} -binding sites. In contrast to Ca^{2+} binding to EF-hand type of sites, which causes substantial conformational changes, Ca^{2+} binding to sites of C₂-domains leads to structural stabilization rather than backbone rearrangements.

Structural determination of other C₂-domains revealed similar designs, but significant differences in the topology of the

Figure 4 Ribbon diagrams of the structures of the C₂A-domain of synaptotagmin I (a) and of the C₂-domain of phospholipase Cδ1 (b). (c) A schematic drawing of the β-strand topologies of the two structures. The locations of the Ca²⁺ clusters (orange) are indicated. Reproduced from Rizo J and Südhof TC (1998) C₂-domains, structure and function of a universal Ca²⁺-binding domain. *Journal of Biological Chemistry* 273: 15879–15882, with permission of the American Society for Biochemistry & Molecular Biology.

arrangement of the β-strands (see Figure 4(c)). It could be shown that the structure of the C₂-domain of protein kinase Cβ is very similar to synaptotagmin I (topology I), whereas the topological arrangement of the structure of the C₂-domain of phospholipase Cδ is significantly different (topology II) (see Figure 4(c)). Phospholipase Cδ contains several protein modules including EF-hand Ca²⁺-binding domains, which provides evidence for the existence of proteins containing EF-hand and non-EF-hand Ca²⁺-binding sites.

An interesting finding concerning important functional differences between Ca²⁺-binding sites of C₂A- and C₂B-domains of synaptotagmin has recently been reported. It has been shown that by mutating an aspartate essential for Ca²⁺ binding to the C₂A-domain into an asparagine, this domain lost its Ca²⁺-dependent binding to phospholipids or to syntaxin.

However, introducing such a mutated synaptotagmin into the germline of *Drosophila* lacking synaptotagmin I that were severely impaired in neurotransmitter release, the mutated synaptotagmin I could fully rescue this defect, indicating that Ca²⁺ binding to the C₂A-domain of synaptotagmin is not essential for neurotransmitter release. However, by replacing an aspartate for asparagine essential for Ca²⁺ binding in the C₂B-domain, this mutated protein could not rescue such a defect in a similar set of experiments suggesting a significant functional difference in Ca²⁺ binding between the C₂A- and C₂B-domains of synaptotagmin I.

In another C₂-domain containing protein, Nedd4, it was demonstrated that binding of Ca²⁺ to the C₂-domain was responsible not only for the localization of the protein but also for part of its function. Nedd4, the neuronal precursor

cell-expressed developmentally downregulated four protein, is a multimodular ubiquitin protein ligase. In humans, there are two Nedd4 genes located on chromosomes 15 and 18, respectively. This enzyme is involved in controlling the turnover of membrane proteins. Four groups of Nedd4 substrates have been identified to date: membrane transporters and ion channels, membrane receptors like EGFR, tumor suppressors, and endocytic regulatory proteins. It was shown that localization of Nedd4 to the apical region of polarized epithelial cells was dependent on the Ca²⁺ binding to its C₂-domain. Here, an important target of Nedd4 is the Na⁺-channel (ENaC), which plays a critical role in Na⁺ homeostasis of epithelial cells. Interestingly, the WW-domain of Nedd4, but not the C₂-domain was required to downregulate EnaC. On the other hand, it was shown that Nedd4 lacking its C₂-domain was still able to ligate ubiquitin to appropriate membrane protein targets such as Gap1, the general amino acid permease, but subsequent internalization by endocytosis, a prerequisite for the downregulation of membrane receptor proteins, was impaired. Recently, Wang et al. (2010) reported that the C₂ domain of Nedd4 is the auto-inhibitory domain for its ubiquitin ligase activity. By binding of Ca²⁺ to the C₂ domain the ubiquitin ligase activity of Nedd4 is activated *in vitro* and *in vivo*. On the other hand, if the C₂ domain is deleted Nedd4 is constitutively activated.

Glossary

Biological minerals Shells and bones.

Calcium complexes Soluble combinations of calcium with ligands.

Calcium ion properties Ion size, ionization potential, and fast exchange.

Fitness The Darwinian concept of being valuable for a biological function.

Messenger function of calcium Calcium moving between internal compartments of a cell or between external and internal zones.

Organelles Mitochondria or chloroplasts. They differ from vesicles in having residual DNA/RNA synthetic systems, although both organelles and vesicles are compartments separated by membranes from the cytoplasm.

Calcium has a special cation, Ca^{2+} , in cellular activity. It is rejected by all cell cytoplasm either to the outside of cells or to the inside of resides. From these stores it is released by events outside eukaryote cells to the cytoplasm and organelles where it activates many processes. Thus, calcium is the dominant messenger, relaying information concerning the environment to activities such as contraction of muscles, release of digestive juices from the pancreas, to hormone release from glands. It is also the major cation in organizing external protein structures and in the formation of biological minerals – shells and bones.

Calcium: The Element and Its Ion, Ca^{2+}

Calcium, atomic number 20, lies in group 2 in the third row of the periodic table and before the first row of transition metals. It resides below magnesium and above strontium and then barium in its group. It has low ionization potentials, giving a rather large calcium ion, Ca^{2+} (radius $1.0\text{\AA}$), which is a rather poor Lewis acid and hence a somewhat poor acid catalyst. However, it can bind quite strongly to certain anion centers. Within its group, the chemistry of the Ca^{2+} ion has close resemblance to that of the larger strontium ion, Sr^{2+} , but differs markedly from the smaller magnesium ion, Mg^{2+} , which is a better Lewis acid.

Calcium, like magnesium, is an abundant element in the universe and on Earth, and its salts are quite soluble in water. Hence, calcium is available in the sea, 10^{-2}M , compared to magnesium at $5 \times 10^{-2}\text{M}$, whereas in freshwater it, like magnesium, is often as high as 10^{-3}M . It is against these background levels in water, especially in the sea, that life evolved.

The calcium ion has three major mass isotopes, 40, 42, and 44, which can be used to follow the reactions of its ions. It can also be followed in biological systems through association with fluorescent organic dyestuffs.

The Aqueous Calcium Ion

The free aqueous calcium ion has a variable fluctuating number of water molecules around it, exceeding six but not

exceeding nine. This loose hydration sphere is common to all cations of a radius greater than $0.8\text{\AA}$. In this way, the calcium ion differs from the magnesium ion, radius $0.6\text{\AA}$, which has a fixed, rather rigid coordination of six water molecules. The differences in structure are reflected in the rates of exchange of the water molecules from their respective coordination spheres, that of magnesium being rather slow, 10^6s^{-1} and that of calcium being close to the diffusion limit of 10^9s^{-1} .

Insoluble Salts

The binding of calcium, a large ion, is less than that of magnesium when the incoming anion is small (e.g., fluoride or hydroxide) and these magnesium salts tend to be the more insoluble. However, larger groups, which include the vast majority of anions (e.g., carbonate, sulfate, and phosphate anions), are more readily accommodated around the larger calcium ion. Hence, we observe that the vast majority of calcium salts are more insoluble than the corresponding magnesium salts. This becomes a feature in organisms, where we find calcium carbonate in shells and calcium phosphate in bones, whereas in plants calcium oxalate is often precipitated. Aberrant precipitation causes stones in animal organs. Among minerals, calcium and magnesium often occur together, as, for example, in dolomite.

Soluble Complex Ions and Their Binding Strengths

Calcium ions do not bind strongly to simple anions in water at pH 7. Thus, complexes with carbonate, sulfate, hydroxide, and phosphate are not of great importance in organisms. However, binding to ligands with several donor atoms can be strong because despite their bulkiness they can be fitted around the large calcium ion. By contrast, the Mg^{2+} ion fails to bind strongly, so these chelating ligands selectively bind calcium relative to magnesium by at least a 1000-fold. Typical examples are proteins both inside the cells and in external circulating fluids. The use of the calcium buffer (ethylene tetra-acetate) depends on this quite strong binding to calcium but weak binding to magnesium at pH 7.

Structures of Calcium Salts and Complexes

The structures of many calcium salts have been determined, and the extremes of their variation are shown even within the allotropic forms of its carbonates. Whereas calcite has a six-coordinate lattice, aragonite has a nine-coordinate structure. These salts have no water of crystallization and both are found in shells. More frequently, when calcium ions are bound to bulky chelating organic ligands in solution, calcium has seven near-neighbors, but the distances from the metal ion to the nearest ligand atom are very irregular, from 2.2 to 3.0 Å. Bound to saccharides or proteins, the ion has this structure, but it fluctuates. It is usual for one or two water molecules to remain bound. The binding ligand atoms are invariably oxygen from such centers as oxyanions, carboxylates, alcohols, carbonyls, and ethers.

Rates of Exchange

The rate of loss of water molecules from around Ca^{2+} , 10^9 s^{-1} , is the rate at which ligands can bind, k_{on} . The rate of leaving is related to the ligand-binding constant, $K = k_{\text{on}}/k_{\text{off}}$, so for $K = 10^6 \text{ M}^{-1}$ the leaving rate is 10^3 s^{-1} . This binding constant is close to that found for several proteins inside cells. The combination of such a protein (e.g., calmodulin) with calcium then provides a response time of 10^3 s^{-1} , as is seen in fast muscle cells. It is the rates of exchange together with the selective binding constants that make calcium an incomparable messenger in aqueous solution.

Biological Salts and Ligand Complexes

The major insoluble calcium salts found in organisms are the fluoride (in krill), carbonates (in shells in at least three allotropic forms), phosphates (in bone), and oxalates (in many plants). There are variable amounts of other metal ions and anions in these salts, so their exact nature is far from simple; for example, bone, hydroxy apatite, does not have an ideal stoichiometric formula and easily incorporates other elements including magnesium and fluoride. The apatite structure is somewhat different in bones of different organisms and even in the teeth and bones of one species (e.g., humans). Calcite is also found in the ears of animals, with a balance function.

In cellular complexes, calcium is bound, seven coordinate, to oxygen (O^-) donor groups of proteins and polysaccharides through both side- and main-chain atoms (e.g., $-\text{OH}$, $>\text{CO}$, CO_2^- ether, and SO_4^{2-}). There is little or no binding to DNA or RNA in cells, in marked contrast to the essential function of magnesium in the structures of these nucleotides. The selective binding arises from the differences in concentration and binding ability.

Concentrations and Selectivity of Binding in Organisms

The ability of calcium ions to precipitate many organic anions including DNA required that one primary necessity of the original life forms, prokaryotes, was the rejection of calcium. Consequently, all organisms hold Ca^{2+} concentrations at

10^{-6} M or below in their cytoplasm using calcium-outward pumps. Magnesium ions do not precipitate organic anions and are found at 10^{-3} M in all cell cytoplasm. Hence, for Ca^{2+} to bind selectively inside cells, its binding constant must be close to 10^6 M^{-1} , whereas that of Mg^{2+} has to be less than 10^3 M^{-1} . This selectivity between the two ions is found for many cytoplasmic messenger proteins, for example, calmodulin, troponin, and S-100. Meanwhile, Ca^{2+} fails to bind to molecules such as adenosine triphosphate (ATP) and DNA, $K = 10^4$, but Mg^{2+} can bind with the same binding constant. Outside cells, both Mg^{2+} and Ca^{2+} are $>10^{-3} \text{ M}$ and in eukaryotes the cell vesicles hold Ca^{2+} at this concentration also. Ca^{2+} can again bind selectively if its binding constant to proteins or now saccharides is $\geq 10^3 \text{ M}^{-1}$, whereas that of Mg^{2+} is less than 10^2 M^{-1} , because both ions are present outside the cells at 10^{-3} M . These constants are found for some coat, blood-clotting, and immune-response proteins and for some vesicle proteins. Note that in higher organisms the free Ca^{2+} concentration in external fluids and vesicles is extremely well controlled and in the extracellular fluid of humans is nearly in equilibrium with the precipitated bone. The further requirement for a messenger activity, that the rate of exchange to the internal proteins be fast, at least 10^3 s^{-1} for calcium, is also met.

Consider now a cytoplasmic concentration in a resting cell of Ca^{2+} of 10^{-7} M and an external or vesicle concentration of 10^{-3} M . Any influx of Ca^{2+} to the cytoplasm from outside through channels will increase Ca^{2+} to 10^{-6} M , which will trigger activity through cytoplasmic protein binding. On closing the channel, the outward pumps will restore rest conditions quickly. The calcium ion is, therefore, able to act as a pulsed messenger. Hence, the combination of sufficiency of binding, of selectivity, of concentration control, and of rates of on/off reactions gives optimal messenger character to this elementary ion. No other ion or molecule could be better.

Overall Functional Fitness of Calcium Ions in Evolution

The properties of the calcium ion, its fast on/off reactions reflecting the structural flexibility of its coordination sphere and its quite strong binding to selected organic ligands, have made it an extremely valuable partner to organic chemicals in almost all forms of life. In the most primitive forms of life, this value is seen not only in protective external constructs (walls) and mineralization, but also in the use of bound calcium in external digestive catalytic enzymes. These functions are found in all other organisms, but the most striking feature of the use of calcium appeared at the time the eukaryotes developed from the prokaryotes. At that time, the problem of coordinating activities of different compartments (vesicles) and the need for an increasing recognition of the environment became critical for the survival of the large eukaryote cells. Cooperation between compartments and sensing required the rapid transfer of information between cellular compartments and from the outside environment, and there is no better possible mode of communication in cellular biology than that which can be derived from the happy coincidental values of the high availability with concentration control and the response properties of the calcium ion. Hence, it was an evolutionary requirement

Table 1 Calcium-controlled events in cells

Activity	Controlled events or systems
Photosynthesis	Dioxygen release
Oxidative phosphorylation	Dehydrogenases
Receptor responses	Nerve synapse; IP ₃ -linked reactions
Contractile devices	Muscle triggering (actomyosin); cell filament controls (tubulins)
Phosphorylation	Activation of kinases, e.g., in fertilization
Metabolism	Numerous enzymes inside cells
Membrane/filament organization	Annexin-like proteins modulate tension
Cell division	S-100 proteins, immune system
Cell death (apoptosis)	Internal proteases
Hormone/transmitter release	Homeostasis
Binding to membranes	C2 domains of enzymes
Cross-linking	Outside cells
Enzyme activation	Outside cells; in membranes

that led to a messenger system in which the calcium ion was the best of all available carriers (Table 1). The protein receptors in the cytoplasm acted as mechanical triggers of action, changing conformation upon binding calcium. They include all muscle responses (troponins), fertilizations, many metabolic responses (calmodulins), genetic activations (possibly S-100 and other proteins), and immune responses (calcineurin). The necessary refinement of the homeostasis of the calcium concentrations increased all the way up to humans and included the control over both the internal cytoplasmic and the external circulating fluid concentrations. In the external fluids, there arose various novel functions that used the calcium ion, including further immune responses and blood-clotting controls in addition to digestive actions. Finally, we must remember that the messenger system from outside to inside the cell was augmented by the further responses, releases due to calcium pulses of chemicals, which caused release from internal vesicles and organelles to both the cytoplasm and the external fluids. Thus, the pulsed calcium ion input to the mitochondria and chloroplasts stimulates the release of energy (ATP) to the cytoplasm, and the release of this ion from vesicles to the external fluids stimulates the release not only of enzymes (e.g., for digestion, general to many organisms) but also of hormones and synaptic messengers, leading to overall homeostatic control. Hence, calcium signaling is central to a huge variety of communication modes leading up to and including synaptic action in the brain. In this homeostasis, we must not forget the buffer action of the bone. The overall fitness of calcium for a multitude of functions is very clear (see Figure 1).

Figure 1 The generalized way in which calcium ions act as a messenger in advanced animal cells. The top of the figure shows the connection between the calcium in the external fluids, bone, and glands and uptake and rejection systems (e.g., the epithelial cells of digestion and the rejection cells of the kidney); H is a hormone. Calcium ions from the circulating fluids together with hormones and Na/K nerve messages activate a large range of cells. The calcium entry is controlled by channels R responding to perturbations. On entering the cell, calcium can release further calcium from vesicles such as the endoplasmic reticulum (ER). The calcium in the cytoplasm can act directly on filaments (F), on mitochondria (M) (or chloroplasts), through transcription factors on the nucleus (N), and on vesicles (V). The vesicles act to release transmitters, hormones, or enzymes. The calcium is removed by pumps (P). The bottom of the diagram shows the effect of general depolarization rather than specific channel activation. This allows calcium entry by electrically operated channels, as, for example, at nerve synapses of the heart.

Glossary

Apoptosis Form of programmed cell death mediated by intracellular proteolytic enzymes known as caspases.

Calbindin D_{9K} Calcium-binding protein of approximately 9000 molecular weight with two calcium binding domains, present in highest concentration in mammalian intestine.

Calbindin D_{28K} Calcium-binding protein of approximately 28 000 molecular weight with four calcium-binding sites, present in highest concentration in avian intestine and in avian and mammalian kidney, brain, and pancreas.

Knock-out mice Genetically engineered mice in which one or more genes have been inactivated through targeted deletions or mutations.

Vitamin D A secosteroid that is synthesized in the skin from 7-dehydrocholesterol by ultraviolet irradiation. Vitamin D is biologically inert and must undergo two successive hydroxylations in the liver and kidney to become the biologically active 1,25-dihydroxyvitamin D₃.

1,25-Dihydroxyvitamin D₃ [1,25(OH)₂D₃] Biologically active metabolite of vitamin D.

Introduction

The calbindins, calbindin-D_{9K} and calbindin-D_{28K}, belong to a family of high-affinity calcium-binding proteins that contains more than 300 members and are characterized by the EF hand structural motif (an octahedral structure consisting of two α -helices connected by a sequence of 12–14 amino acids that constitute a high-affinity calcium-binding site). Calbindin was the first identified target of vitamin D action. Calbindin-D_{28K}, a protein of approximately 28 000 molecular weight which has four high-affinity binding sites for calcium, is present in highest concentrations in avian intestine and in avian and mammalian kidney, brain, and pancreas. Calbindin-D_{28K} is highly conserved in evolution. Calbindin-D_{9K}, a protein of approximately 9000 molecular weight which has two calcium-binding domains, is present in highest concentrations in mammalian intestine and, unlike calbindin-D_{28K}, is not evolutionarily conserved. It is present only in mammals. There is no amino acid sequence homology between calbindin-D_{9K} and calbindin-D_{28K}. The characterization, distribution, functional significance, and regulation of these proteins as well as recent findings using calbindin knock-out mice are reviewed.

Calbindin-D_{28K}

Characterization and Tissue Distribution

Calbindin-D_{28K}, previously known as the vitamin D-dependent Ca²⁺-binding protein (CaBP), was initially discovered in avian intestine by Wasserman and Taylor in 1966. In 1985, the protein became officially known as calbindin-D_{28K}. Through examination of the protein's distribution in tissues and colocalization with the vitamin D receptor (VDR), significant advances have been made in our understanding of the vitamin D endocrine system.

Chicken and mammalian calbindin-D_{28K} are single-chain polypeptides containing 261 amino acid residues, have a

molecular weight of approximately 28 000 based on migration on sodium dodecyl sulfate-polyacrylamide gels, and contain blocking groups at the amino terminus. Calbindin-D_{28K} is highly conserved in evolution, with 98% homology in mammalian calbindin-D_{28K} sequences and 79% homology between mammalian and chicken sequences. Conservation of calbindin-D_{28K} sequences suggests its essential physiological role in mediating intracellular calcium-dependent processes.

Calbindin-D_{28K}, an acidic and heat-stable protein, is a member of the EF-hand protein family that binds Ca²⁺ with high affinity ($K_d = 10^{-8}$ – 10^{-6}). The EF-hand domain is a 29–30-amino-acid octahedral structure consisting of two α helices separated by a highly conserved sequence of 12 amino acids. The 12-amino-acid loop contains side chain oxygens essential for binding the divalent Ca²⁺ cation. Though calbindin-D_{28K} contains six EF-hand domains, only four actively bind Ca²⁺ (Figure 1).

The human calbindin-D_{28K} gene (symbol: *CALB1*) is located on chromosome 8, spans 24 kb, and consists of 11 exons.

Since its discovery in avian intestine, calbindin-D_{28K} has been identified in many other tissues including kidney and bone and in non-serum Ca²⁺-regulating tissues such as pancreas, testes, and brain. Table 1 summarizes the distribution of calbindin-D_{28K} in a variety of tissues and species.

Proposed Functional Significance

Intestine

Calbindin-D_{28K} in avian intestine (as well as calbindin-D_{9K} in mammalian intestine) are markedly induced by 1,25(OH)₂D₃ and are localized in the cytoplasm of absorptive cells, supporting a proposed role in intestinal calcium absorption (also see section on calbindin-D_{9K}). However, calbindin may also act in the intestine by buffering calcium, protecting against calcium-mediated cell death during 1,25(OH)₂D₃-dependent intestinal calcium transport.

Figure 1 Computational model of disulfide-bonded calbindin-D_{28K}. Calbindin-D_{28K} is made up of six EF hand domains, four of which bind calcium. Calcium-binding EF hands are shown, with calcium ions shown as spheres. Mass spectrometry and nuclear magnetic resonance experiments have shown that EF hands 1, 3, 4, and 5 bind calcium and that calcium ions are sequentially bound with EF hand 1 first, followed by EF hand 4 and 5 and lastly EF hand 3. Reproduced from figure 7 in Hobbs CA (2009) Structural characterization of the conformational change in calbindin-D_{28K} upon calcium binding using differential surface modification analyzed by mass spectrometry. *Biochemistry* 48(36): 8603–8314, with permission from ACS.

Table 1 Distribution of calbindin-D_{28K}

Avian intestine
Avian, reptilian, amphibian, and mammalian kidney
Hen egg-shell gland (uterus)
Mouse reproductive tissues (uterus, oviduct, ovary)
Avian and mammalian beta cells of the pancreas
Alpha cells of the rat pancreas
Rat and chick growth cartilage
Ameloblasts and osteoblasts of rodent teeth; mouse osteoblasts
Brain (avian, reptilian, amphibian, molluscan, fish, and mammalian brain)

Kidney

In mammals, chickens, and reptiles, renal calbindin-D_{28K} is found exclusively in the cytosol, and to a lesser extent the nucleus, of distal convoluted tubule and connecting tubule cells of the distal nephron. It has been shown that the VDR is also predominantly found in the distal nephron. In the distal nephron, 1,25(OH)₂D₃ enhances PTH-mediated uptake of Ca²⁺ at the apical membrane of the distal tubule cell. Although 1,25(OH)₂D₃ has been reported to induce calbindin-D_{28K}, little is known regarding the exact role of vitamin D-inducible calbindin in Ca²⁺ transport in the distal nephron. In a process similar to intestinal Ca²⁺ absorption, renal transcellular Ca²⁺ transport involves Ca²⁺ entry through an apical Ca²⁺ channel, diffusion of Ca²⁺ through the cell interior, and active Ca²⁺ extrusion from the basolateral membrane through a

Ca²⁺-dependent adenosine triphosphatase (ATPase). As has been suggested for intestinal calbindin, renal calbindin-D_{28K} may act to shuttle Ca²⁺ through the cell interior to the basolateral membrane and to buffer Ca²⁺ and protect against Ca²⁺-mediated cell death.

The transient receptor potential vanilloid-subtype 5 (TRPV5) is an epithelial Ca²⁺ channel that acts as a gatekeeper of apical Ca²⁺ entry during active reabsorption. TRPV5 and calbindin-D_{28K} are co-expressed in the distal nephron and are co-regulated by 1,25(OH)₂D₃ and dietary Ca²⁺. Under conditions of low intracellular Ca²⁺, calbindin-D_{28K} directly interacts with TRPV5 at the apical membrane and has been shown to modulate the activity of the epithelial Ca²⁺ channel. These findings suggest an additional role for renal calbindin-D_{28K} as a modulator of calcium influx.

Bone

In rats and chicks, calbindin-D_{28K} has been found in chondrocytes of growth plate cartilage suggesting a possible role for calbindin-D_{28K} in cartilage calcification and chondrocyte maturation and differentiation. Calbindin-D_{28K} has also been localized to highly specialized cells of rodent teeth, including ameloblasts, odontoblasts, and osteoblasts. Through Ca²⁺ handling, calbindin-D_{28K} may be involved in the mineralization of tissues, enamel, dentine, and bone.

Through inhibition of caspase-3, a key mediator of apoptosis, calbindin-D_{28K} has also been shown to protect against tumor necrosis factor (TNF)-induced cell death in osteoblastic cells and glucocorticoid-induced cell death in osteoblastic and osteocytic cells. The ability of calbindin-D_{28K} to inhibit caspase-3 is independent of its Ca²⁺-binding characteristics. As a natural non-oncogenic inhibitor of caspase-3, calbindin-D_{28K} may be an important target in the therapeutic prevention of bone cell degeneration.

Pancreas

Calbindin-D_{28K} has been identified in human pancreatic islet cells in addition to chick insulin-producing beta cells and alpha and beta cells of the rat pancreas. It has been suggested that calbindin-D_{28K} may modulate depolarization-stimulated insulin release by regulating intracellular Ca²⁺. Further studies have indicated that calbindin-D_{28K}, by acting as a Ca²⁺ buffer, can prevent Ca²⁺-mediated mitochondrial damage and subsequent free radical formation. In this way, calbindin-D_{28K} protects against cytokine-mediated destruction of beta cells. These findings have important implications in the treatment of type 1 diabetes and the prevention of autoimmune destruction of pancreatic beta cells. Calbindin-D_{28K} has also been shown to regulate Ca²⁺ influx in pancreatic beta cells via L-type voltage-dependent Ca²⁺ channels. In rat pancreatic beta cells, the alpha₁ subunit of the L-type channel can interact with calbindin-D_{28K} and L-type channels show enhanced sensitivity to Ca²⁺-dependent inactivation in the presence of calbindin-D_{28K}. Together, these findings indicate that pancreatic calbindin-D_{28K} is involved in intracellular Ca²⁺ homeostasis as well as modulation of Ca²⁺ influx.

Reproductive tissues

Calbindin-D_{28K} has been localized in spermatogonia and spermatocytes of the seminiferous tubules and some interstitial

Leydig cells in chick and rat testes. The involvement of calbindin-D_{28K} in spermatogenesis has been suggested.

In addition, calbindin-D_{28K} is also localized in the tubular gland cells of the chick shell gland which are involved in Ca²⁺ secretion during formation of the egg shell.

In female mice (but not rats), calbindin-D_{28K} is present in reproductive tissues including the endometrium and glandular epithelium of the uterus, the oviduct epithelium, and primary follicles of the ovary. Calbindin is not regulated by 1,25(OH)₂D₃ in these tissues. Estradiol has been shown to regulate calbindin-D_{28K} in the uterus. Although the exact role of uterine calbindin-D_{28K} is not known, it has been suggested that calbindin-D_{28K} may act to facilitate transcellular Ca²⁺ transport in epithelial cells of the uterus.

Nervous tissue

In a wide variety of species, including mammals, avians, reptiles, amphibians, fish, and mollusks, calbindin-D_{28K} in the brain is vitamin D independent and is found in most neuronal cell groups and in some epithelial cells lining the ventricular system. Neurons containing calbindin-D_{28K} are found in layers 2–4 of the cerebral cortex, the hippocampus, the cerebellum (specifically in Purkinje cells) as well as the hypothalamus, amygdala, pyriform region, and thalamus. Furthermore, calbindin-D_{28K} is found in specific neuronal sensory cells of the visual and auditory systems. These cells include cochlear and vestibular hair cells of the inner ear, avian basilar papilla, photoreceptor cells (cone but not rod cells) of avian and mammalian retina, and in pineal transducers (conelike, modified photoreceptor cells (pinealocytes)).

It has been suggested that neuronal calbindin, by buffering Ca²⁺, can limit Ca²⁺ influx and regulate intracellular Ca²⁺ responses to physiological stimuli. Through maintenance of Ca²⁺ homeostasis, calbindin-D_{28K} can protect neurons against calcium-mediated neurotoxicity and modulate synaptic transmission. Studies examining the effect of calbindin-D_{28K} overexpression, either by introduction of exogenous calbindin-D_{28K} via the whole-cell patch-clamp method or by transfection and overexpression of calbindin-D_{28K} have demonstrated that calbindin-D_{28K} can modify Ca²⁺ signals to alter synaptic plasticity and neuronal firing patterns.

The role of calbindin-D_{28K} in influencing physiological responses is further suggested in studies examining the expression of calbindin-D_{28K} in mouse suprachiasmatic nucleus (SCN). In mammals, the SCN is the fundamental regulator of circadian function and entrainment. In the mouse SCN, calbindin-D_{28K} is markedly expressed during development and is co-expressed in adult melanopsin-producing retinal ganglion cells. In calbindin-D_{28K}-null mutant mice significant abnormalities are observed in circadian locomotor rhythmicity and entrainment to light/dark cycles, though response to acute light remains normal. These findings suggest a role for calbindin-D_{28K} in circadian organization and light transduction.

Studies of ischemic injury, seizure activity, and chronic neurodegeneration (Alzheimer's, Huntington's, and Parkinson's diseases) have suggested a correlation between decreased neuronal calbindin-D_{28K} and neurodegeneration. With reduced levels of calbindin, neurons may be unequipped to buffer excess intracellular Ca²⁺, resulting in calcium-mediated neuronal damage and cell death. In primary cultures of neuronal

cells and in neuronal cell lines transfected with the calbindin-D_{28K} gene, calbindin-D_{28K} has been shown to increase the survival of cells injured in response to hypoglycemia and amyotrophic lateral sclerosis IgG-mediated cytotoxicity. In rats, it has been shown that pretreatment with a calbindin-D_{28K} fusion protein (protein transduction domain (PTD)-calbindin-D_{28K}) attenuates neuronal insults induced by ischemia and reperfusion. PTDs are small peptides that serve to deliver larger molecules into a variety of cells, including those of the blood-brain barrier, without employing traditional endocytic mechanisms. PTD-fused proteins have been shown to retain their biologic activity and thus represent a potentially novel approach for the treatment of neuropathies, including ischemic injury.

Calbindin-D_{28K} has also been shown to prevent apoptosis in neural cells expressing mutant presenilin 1 (PS-1), which is causally linked to about 50% of cases in early-onset familial Alzheimer's disease. Amyloid β peptide (A β) comprises the major component of plaques in Alzheimer's disease and has been reported to induce neuronal damage in cells sensitized to apoptosis by mutant PS-1 via oxidative stress mechanisms and disruption of calcium balance. Calbindin-D_{28K} protects against the proapoptotic action of mutant PS-1 by restoring intracellular Ca²⁺ homeostasis, thereby maintaining mitochondrial integrity and function.

Regulation

Regulation by 1,25(OH)₂D₃

1,25(OH)₂D₃ is known to induce calbindin-D_{28K} in the avian intestine and kidney and in mammalian kidney. Only modest responses in the activities of the chicken and mouse calbindin-D_{28K} promoters to 1,25(OH)₂D₃ have been observed. Such findings reflect the small transcriptional response of the calbindin-D_{28K} gene to 1,25(OH)₂D₃. However, calbindin-D_{28K} messenger RNA (mRNA) is largely induced long after 1,25(OH)₂D₃ treatment, suggesting mostly posttranscriptional mechanisms for the accumulation of calbindin-D_{28K} mRNA. These findings illustrate the complexity of 1,25(OH)₂D₃ action on calbindin-D_{28K} and suggest that a model beyond the conventional hormone receptor-transcriptional activation model is needed to understand calbindin-D_{28K} regulation.

Regulation by other steroids and factors

Studies have shown that calbindin-D_{28K} gene expression may be regulated by factors other than 1,25(OH)₂D₃. Vitamin D-treated chicks that are given glucocorticoids show decreased levels of calbindin-D_{28K} mRNA and protein in intestine and inhibition of intestinal Ca²⁺ absorption (mammalian calbindin-D_{9K} in intestine is also downregulated by glucocorticoids; see section in calbindin-D_{9K}). Alterations in dietary Ca²⁺ and phosphorus have also been shown to modulate avian intestinal and renal calbindin-D_{28K} gene expression.

Studies have suggested that gender-specific hormones may also modulate calbindin-D_{28K} expression. As previously discussed, calbindin-D_{28K} is found in the avian egg-shell gland and in the reproductive tissues of female mice. In *in vivo* experiments examining the avian egg-shell gland, estradiol is shown to induce calbindin-D_{28K}. By contrast, in female mice, calbindin-D_{28K} gene expression is downregulated by estradiol in the uterus. The differing effects of estradiol in chick and mouse suggest

species-specific regulation of calbindin-D_{28K} by estradiol. Gender differences have been reported to influence renal handling of Ca²⁺ as male mice display greater urinary Ca²⁺ loss than female mice. Male mice also show significantly decreased levels of TRPV5 and calbindin-D_{28K} compared to female mice. Furthermore, androgen-deficient male mice show increased renal TRPV5 and calbindin-D_{28K} mRNA and protein. This increase is suppressed by testosterone treatment and is not accompanied by significant differences in serum estrogen, parathyroid hormone, or 1,25(OH)₂D₃ levels. These findings suggest that the inhibitory actions of androgens on TRPV5 and calbindin-D_{28K} may, in part, explain gender differences in renal Ca²⁺ reabsorption.

In the central nervous system, where calbindin-D_{28K} is detected in significant amounts, calbindin-D_{28K} regulation is independent of 1,25(OH)₂D₃. In contrast to the action of 1,25(OH)₂D₃ on intestinal and renal calbindin-D_{28K} gene expression, 1,25(OH)₂D₃ does not affect levels of neuronal calbindin-D_{28K}. On the other hand, TNFs and neurotropic factors including neurotrophin 3 (NT-3), brain-derived neurotrophic factor (BDNF), and fibroblast growth factor (FGF), have been shown to induce calbindin-D_{28K} in rat hippocampal cultures. The induction of calbindin-D_{28K} by these factors may be, in part, a mechanism against cytotoxic injury, as neurotropic factors have been shown to protect against excitotoxic neuronal damage. The cell-specific regulation of neuronal calbindin-D_{28K} by a variety of factors is further supported by studies showing induction of calbindin-D_{28K} by corticosterone in the CA1 region of rat hippocampus, retinoic acid in medulloblastoma cells that pose a neuronal phenotype, insulin-like growth factor I (IGF-I) in cultured Purkinje cells, and by IFG1 and insulin in rat embryonic neuronal cells.

Though calcium-binding proteins were the first identified targets of 1,25(OH)₂D₃ action, studies examining the complexity in calbindin-D_{28K} regulation illustrate that its utility extends beyond the traditional paradigm of the vitamin D endocrine system.

Calbindin-D_{28K} Knockout Mice

The phenotype of calbindin-D_{28K}-null mutant mice is impaired motor coordination associated with alterations in Ca²⁺ signaling in Purkinje cells. Calbindin-D_{28K}(-/-) mice show normal levels of serum-ionized calcium, phosphorus, and PTH, and normal urinary calcium and phosphorus. Histological examination reveals normal bone structure. In order to further determine the *in vivo* functional significance of mammalian calbindin-D_{28K} VDR/calbindin-D_{28K} double KO mice were generated. Phenotypic characteristics of mice deficient only in VDR include secondary hyperparathyroidism, rickets, and osteomalacia, and renal calbindin-D_{9K} is reduced to 10% of typical levels (thus, in these mice, calbindin-D_{9K} would not compensate for the loss of calbindin-D_{28K}). Compared to VDR KO mice, VDR/calbindin-D_{28K} double KO mice experience a higher loss of urinary calcium and as a result, more pronounced effects of calcium dysregulation including severe hyperparathyroidism, greater bone resorption, lower body mass index (BMD), and increased osteoid accumulation. For both VDR KO and double KO mice, a high Ca²⁺ diet can restore normal levels of serum ionized and urinary calcium. However, unlike in VDR KO mice, high calcium supply cannot

completely rescue the skeletal abnormalities in double KO mice. These findings provide *in vivo* evidence for the importance of calbindin-D_{28K} in maintaining calcium homeostasis.

Studies were also done comparing TRPV5(-/-), calbindin-D_{28K}(-/-), and TRPV5/calbindin-D_{28K} double KO mice. Double KO mice show hypercalciuria similar to TRPV5(-/-) mice, though calbindin-D_{28K}(-/-) mice do not experience comparable urinary Ca²⁺ loss. TRPV5(-/-) and double KO mice also exhibit similar increases in renal calbindin-D_{9K} expression and upregulation of duodenal calbindin-D_{9K} and TRPV6, resulting in increased intestinal Ca²⁺ absorption (to compensate, at least in part, for the urinary Ca²⁺ loss). Calbindin-D_{28K}(-/-) mice do not exhibit alterations in intestinal Ca²⁺ absorption and expression of calbindin-D_{9K} and TRPV6 remain unchanged. The similarities seen in TRPV5(-/-) and TRPV5/calbindin-D_{28K} double KO mice provide evidence that TRPV5-facilitated Ca²⁺ entry in the distal convoluted tubule may be the rate-limiting step in active Ca²⁺ reabsorption. Loss of calbindin-D_{28K}, on the other hand, may be compensated by upregulation of calbindin-D_{9K}.

Calbindin-D_{28K} Summary

Calbindin-D_{28K} is highly conserved in evolution, suggesting a fundamental role for calbindin-D_{28K} in mediating intracellular calcium-dependent processes. Calbindin-D_{28K} is regulated by 1,25(OH)₂D₃ in avian intestine and in avian and mammalian kidney. Calbindin-D_{28K} is present in numerous other tissues including brain, pancreas, and uterus and is regulated by factors other than 1,25(OH)₂D₃. Evidence suggests that calbindin-D_{28K} is involved in protection against apoptotic cell death by buffering calcium and by inhibiting caspase-3. Additional functions of calbindin-D_{28K} include maintenance of intracellular calcium homeostasis and modulation of calcium influx.

Calbindin-D_{9K}

Characterization and Tissue Distribution

Kallfelz, Taylor, and Wasserman first identified a vitamin D regulated 9000-molecular-weight calcium-binding protein in rat intestine in 1967 (which was later called 'calbindin-D_{9K}'). It is a cytosolic calcium-binding protein found only in mammals. Calbindin-D_{9K} contains 79 amino acid residues (9016 molecular weight based on amino acid sequence), is acidic, and heat stable. There is 78% and 74% homology of the human calbindin-D_{9K} sequence to that of the rat and mouse respectively. Calbindin-D_{9K} contains two EF hand domains of 29 and 31 amino acids. Each domain binds one calcium. It is related to the S100 family of calcium-binding proteins. The human calbindin-D_{9K} gene (symbol: *CALB3*) spans 5.5 kb and consists of three exons. The chromosomal localization of the human calbindin-D_{9K} gene is assigned to Xp22.2.

Calbindin-D_{9K} is most abundant in mammalian intestine. It is found in lower concentrations in mouse kidney and neonatal rat kidney (in the distal nephron), placenta of rats and mice, in rat uterus, rat lung and in ameloblasts and osteoblasts of rodent teeth. Table 2 summarizes the distribution of calbindin-D_{9K} in a variety of tissues and species.

Table 2 Distribution of calbindin-D_{9k}

Mammalian intestine
Mouse and neonatal rat kidney
Rat and mouse yolk sac
Rat uterus
Rat and mouse placenta
Rat growth cartilage
Ameloblasts and osteoblasts of rodent teeth
Rat lung

Proposed Functional Significance

Intestine and calbindin-D_{9k} KO mice

Similar to studies of calbindin-D_{28k} in avian intestine, it is thought that intestinal calbindin-D_{9k}, which is markedly induced by 1,25(OH)₂D₃, acts to facilitate the diffusion of calcium through the cell interior toward the basolateral membrane. However, recent studies using calbindin-D_{9k} KO mice have shown that calbindin-D_{9k} is not required for 1,25(OH)₂D₃-induced active intestinal calcium transport. Active intestinal calcium transport is similarly induced in response to a low calcium diet or 1,25(OH)₂D₃ treatment in both calbindin-D_{9k} KO mice and wild-type mice. In addition, calbindin-D_{9k} KO mice are able to maintain normal serum calcium levels regardless of age or sex. These findings suggest that calbindin-D_{9k} may be compensated for by another factor or that calbindin-D_{9k} may have another role in intestine, for example, as a modulator of the activity of TPRV6 (the vitamin D inducible epithelial calcium channel present in the intestine) and/or as an intracellular calcium buffer to prevent toxic levels of calcium from accumulating in the intestine.

Reproductive tissues

Calbindin-D_{9k} is present in placenta of rats and mice and in rat endometrium and myometrium. Since calbindin-D_{9k} in placenta increases at the end of gestation when there is increased calcium need by the fetus, it has been suggested that calbindin-D_{9k} may have a role in transporting calcium from mother to fetus. The presence of calbindin-D_{9k} in myometrium suggests the involvement of calbindin in modulation of intracellular calcium which may alter the frequency and strength of uterine contractions. Since calbindin-D_{9k} KO mice reproduce similar to wild-type mice and calbindin-D_{9k} KO pups are indistinguishable from wild-type pups, the absence of calbindin-D_{9k} in placenta and myometrium may be compensated for by another factor.

Regulation

Similar to avian intestinal calbindin-D_{28k}, intestinal calbindin-D_{9k} is regulated by 1,25(OH)₂D₃ by a small rapid transcriptional response followed by a posttranscriptional effect. Besides VDR, it has been shown that the intestine-specific transcription factor caudal homeobox-2 (Cdx-2) is also important for the transcription of the calbindin-D_{9k} gene.

In addition to 1,25(OH)₂D₃, glucocorticoids also regulate intestinal calbindin-D_{9k}. *In vivo* treatment of mice with glucocorticoids reduces the expression of duodenal calbindin-D_{9k}

mRNA. The reduction in calbindin-D_{9k} mRNA is associated with diminished intestinal calcium absorption. It remains to be determined whether the *in vivo* effects of glucocorticoids on intestinal calbindin-D_{9k} are due to a direct effect of glucocorticoids on the calbindin-D_{9k} gene.

In the rat uterus, calbindin-D_{9k} is induced by estradiol but is unaffected by 1,25(OH)₂D₃ treatment. An estrogen responsive element that mediates the transcriptional regulation of the calbindin-D_{9k} gene has been identified, indicating a direct effect of estradiol on the calbindin-D_{9k} gene.

Calbindin-D_{9k} Summary

Calbindin-D_{9k} is present only in mammals. It is not homologous to calbindin-D_{28k} but rather belongs to the S100 family of calcium-binding proteins. Calbindin-D_{9k} is regulated by 1,25(OH)₂D₃ in intestine and kidney. Although calbindin-D_{9k} is present in other tissues (uterus, placenta, and bone), it has a more restricted tissue distribution compared to calbindin-D_{28k}. Studies in calbindin-D_{9k} KO mice suggest that calbindin-D_{9k} may be compensated for by another factor yet to be identified.

Conclusion

Calbindin-D_{28k} and calbindin-D_{9k} can no longer be viewed exclusively as vitamin D-dependent targets. Regulatory control of calbindin is complex and involves factors other than 1,25(OH)₂D₃, providing evidence that calbindins play a role beyond the traditional model of the vitamin D endocrine system. Calbindin-D_{28k} and calbindin-D_{9k} are found in variety of tissues and species (see [Tables 1](#) and [2](#)) and demonstrate many different tissue-specific functions. Recent studies have provided new insight into the mechanism of action of the calbindins, including the maintenance of intracellular calcium homeostasis, modulation of calcium influx, and protection against apoptosis.

Calcium-Buffering Proteins: ER Luminal Proteins

J Groenendyk and M Michalak, University of Alberta, Edmonton, AB, Canada

© 2013 Elsevier Inc. All rights reserved.

Glossary

Calreticulin Multifunctional Ca^{2+} binding/buffering endoplasmic reticulum (ER) resident chaperone. The protein is responsible for the buffering of over 50% of ER luminal Ca^{2+} and for assisting in the folding of newly synthesized glycoproteins.

Chaperones Molecules that bind to misfolded proteins and assist in their folding and posttranslational modification.

Endoplasmic reticulum (ER) Intracellular organelle involved in many cellular functions including modulation of Ca^{2+} homeostasis, protein synthesis and modification, and lipid synthesis.

KDEL This is a sequence in the amino acid structure of a protein which keeps it from secreting from the ER. It also targets proteins from other locations (such as the cytoplasm) to the ER. Proteins can only leave the ER after this sequence has been cleaved off. The KDEL sequence is responsible for retrieval of ER luminal proteins from the Golgi apparatus. The abbreviation KDEL is formed by the corresponding letters to each amino acid. This letter system was defined by the IUPAC and IUBMB in 1983, and is as follows: K, lysine; D, aspartic acid; E, glutamic acid; L, leucine.

Protein disulfide isomerase Belonging to a family of proteins containing thioredoxin, they modify and catalyze the formation of disulfide bonds in newly synthesized proteins.

Ca^{2+} buffering endoplasmic reticulum (ER) proteins are ER resident proteins that bind Ca^{2+} with a high capacity. They play an important role in the maintenance of resting free Ca^{2+} concentration in the lumen of ER and subsequently in the modulation of cellular Ca^{2+} homeostasis. This is critical because Ca^{2+} is a universal intracellular signaling molecule, which controls numerous developmental and cellular pathways. Changes in Ca^{2+} concentration affect processes as diverse as learning and memory, secretion, contraction and relaxation, membrane excitability, cell motility, cytosolic and mitochondrial metabolism, protein and lipid synthesis, cell cycle, apoptosis, organellar trafficking, and protein folding and quality control. Therefore, it is of the utmost importance that Ca^{2+} homeostasis is tightly regulated in all cells. This is accomplished by a variety of Ca^{2+} transporting, binding, and buffering proteins, which are found in many cellular compartments.

The ER and Ca^{2+} Homeostasis

The ER is one of the most important intracellular Ca^{2+} buffering and storage organelles and performs a vital function during Ca^{2+} signaling with communication to the plasma membrane Ca^{2+} channels, controlling cytosolic Ca^{2+} concentration and fluctuations. Moreover, persistent oscillation of ER luminal Ca^{2+} concentration functions as a signaling event for several ER functions, including protein and lipid synthesis. In response to a variety of external stimuli, Ca^{2+} is released from the lumen of the ER into the cytosol, via the inositol-1,4,5-triphosphate receptor (InsP_3R) and/or the ryanodine receptor (RyR) Ca^{2+} channels. Some Ca^{2+} also enters the cytosol from the extracellular environment, via Ca^{2+} channels in the plasma membrane. Most of the released Ca^{2+} is taken up back into the lumen of the ER via the sarcoplasmic-endoplasmic-reticulum Ca^{2+} -adenosine triphosphatase (ATPase) (SERCA). Some of

the Ca^{2+} is also removed from the cytosol by the plasma membrane Ca^{2+} -ATPase and the Na^+ - Ca^{2+} exchanger. Within the ER, Ca^{2+} is bound to and buffered by high concentrations of luminal Ca^{2+} -binding proteins. A decrease in ER Ca^{2+} levels leads to interrupted trafficking from the ER, delayed transport of molecules across the nuclear pore, and repressed chaperone function. The resting free cytosolic Ca^{2+} concentration has to be sustained at an extremely low level (sub-micromole), so that only tiny fluctuations (microdomains) in local Ca^{2+} levels can trigger a signaling event. This is achieved by actively pumping Ca^{2+} from the cytosol, either into the ER or out of the cell. Extracellular Ca^{2+} concentration is in excess of 2 mM, two orders of magnitude higher than free cytosolic Ca^{2+} concentration, which is about 100 nM, while the free ER Ca^{2+} concentration is approximately 200 μM , with total ER Ca^{2+} concentration up to 1 mM. Ca^{2+} homeostasis and signaling are maintained by controlling Ca^{2+} release from the ER by the InsP_3R and RyR , whereas the ER stores are refilled by the SERCA. Ca^{2+} is also transported out of the cytosol into the extracellular fluid via the sodium- Ca^{2+} exchanger (NCX) and the plasma membrane Ca^{2+} -ATPase (PMCA). Ca^{2+} -binding and buffering proteins play an important role in the translation, amplification, and protraction of Ca^{2+} signals, performing essential negative and positive feedback roles during Ca^{2+} trafficking and ultimately facilitating cells to generate rapid changes in local Ca^{2+} levels. The Ca^{2+} present in the ER stores serves as a source of easily releasable Ca^{2+} , and is also important as a regulator of a number of ER enzymes and proteins, including feedback regulation of the InsP_3R , the RyR , and SERCA. Coordination of ER luminal Ca^{2+} release and extracellular Ca^{2+} influx into the cytosol is critical as sustained cytosolic Ca^{2+} levels are cytotoxic and lead to apoptosis. Overall, it is clear that the ER may be defined as a multifunctional organelle able to detect and integrate incoming signals, modulate its own luminal dynamics, and generate output signals in response to environmental changes.

Ca²⁺ Buffering in the ER Lumen

The lumen of the ER contains spatially and temporally localized Ca²⁺ microdomains involved in downstream Ca²⁺ signaling. This is characterized by the heterogeneity in the localization of Ca²⁺ channels, including the InsP₃R, as well as Ca²⁺ buffering proteins, such as calsequestrin, in the lumen of the ER. This was discovered by using a luminal Ca²⁺ sensor such as ER targeted recombinant aequorin as well as electron microscopy, demonstrating an electron-dense network of calsequestrin in the terminal ends of the cisternae. Free luminal concentrations of Ca²⁺ range from 5 mM to 100 μM with spatial organization of intracellular Ca²⁺ appearing to depend on the strategic distribution of ER Ca²⁺ stores. These may be specific domains that trigger Ca²⁺ puffs, spikes, waves, and oscillations, involved in specific cellular functions including excitation-contraction and Ca²⁺ signaling. For example, the clustering of IP₃R in the membrane of the ER is suggested to regulate the propagation of Ca²⁺ waves with global repositioning of InsP₃R observed during long-term agonist stimulation in a smooth muscle cell line. In addition, activation of neurotrophils triggers whole cell shape change accompanied by dynamic relocation of ER Ca²⁺ stores. Recent work demonstrates that protein-protein interactions are chiefly responsible for the clustering of the InsP₃R in rat basophilic leukemia cells. In total, the lumen of the ER contains 1–3 mM Ca²⁺, a concentration similar to that in the extracellular space. A small portion of this ER luminal Ca²⁺ is not buffered by Ca²⁺ binding to proteins and is considered free. Resting free Ca²⁺ concentrations in the ER vary from 100 to 400 μM, while those in the cytosol are in the nanomolar range. The actual resting free Ca²⁺ concentration in the ER is determined by the balance between the rates of Ca²⁺ uptake and Ca²⁺ leak and by the extent of buffering by the resident Ca²⁺-binding proteins.

Most of the Ca²⁺ in the lumen of the ER is bound to the Ca²⁺-binding molecular chaperones that are resident there. These proteins maintain specific concentration gradients of Ca²⁺ in the ER and localize Ca²⁺ to the sites of release. They also directly affect both the Ca²⁺ storage capacity of the ER and the free Ca²⁺ concentration under resting conditions and after cellular stimulation. Table 1 shows a list of ER proteins that are involved in buffering Ca²⁺ in the ER lumen. There are two major classes of ER Ca²⁺-binding proteins. Class I, the larger of the two, represents proteins which bind Ca²⁺ with relatively high capacity and low affinity. These proteins contain a large proportion of acidic amino acid residues that are involved in the high-capacity and low-affinity Ca²⁺ binding. Their Ca²⁺-binding capacity varies from as little as 2 mol of Ca²⁺ per mole of protein to as much as 50 mol of Ca²⁺ per mole of protein. The high-capacity Ca²⁺-binding sites have a relatively low affinity for Ca²⁺ ($K_d = 1\text{--}2\text{ mM}$), which parallels the relatively high content of Ca²⁺ in the ER lumen. These Ca²⁺-binding proteins are responsible for Ca²⁺ storage in the lumen of the ER/sarcoplasmic reticulum (SR), and they effectively determine the capacity of these intracellular organelles for Ca²⁺. In contrast, class II represents Ca²⁺-binding proteins in the lumen of the ER that bind Ca²⁺ with relatively high affinity and low capacity. The function of these high-affinity-binding sites is

Table 1 Ca²⁺-binding proteins of the endoplasmic reticulum lumen

Protein name	Ca ²⁺ binding (mole/mole of protein)	Gene knockout mouse phenotype
<i>Class I proteins</i> (high-capacity and low-affinity Ca ²⁺ proteins)		
Calreticulin	25	Embryonic lethal E13.5
Grp 94/endoplasmic	10	Embryonic lethal E7.5
Grp 78/BiP	Binds Ca ²⁺	Embryonic lethal E3.5
PDI family		
PDI	20	Not investigated
ERp72	12	Not investigated
ERCalcistorin/PDI	20	Not investigated
P5	Binds Ca ²⁺	Not investigated
ERp57	Not investigated	Embryonic lethal E13.5
ERp44	Not investigated	Not investigated
ERp29	Not investigated	Not investigated
Calsequestrin	50	Not lethal – disrupted Ca ²⁺ homeostasis in muscle
<i>Class I/II protein</i> (contains EF-hand Ca ²⁺ -binding motif but binds with low affinity)		
Stim1	$K_d = 0.6\text{ mM}$ (low affinity)	Neonatal lethality
<i>Class II proteins</i> (contain EF-hand Ca ²⁺ -binding motifs and bind 6–7 mol of Ca ²⁺ /mole of protein with high affinity)		
Reticulocalbin	High affinity	Not investigated
Cab45	High affinity	Not investigated
Calumenin	High affinity	Not investigated
ERC55	High affinity	Not investigated
Crocalbin/CBP-50	High affinity	Not investigated

not obvious, given the high concentrations of Ca²⁺ in the lumen of the ER. It is thought that they might play a structural role, or that they might be responsible for the regulation/maintenance of specific protein-protein interactions. Several of the class II proteins contain a classic EF-hand Ca²⁺-binding site, previously identified in many cytosolic proteins that bind Ca²⁺ with high affinity.

A characteristic common to proteins in both classes is that they contain an N-terminal signal sequence that targets them to the lumen of the ER. They also terminate with a KDEL (K, lysine; D, aspartic acid; E, glutamic acid; L, leucine) like amino acid sequence that is responsible for their continual retrieval back to the ER lumen. Finally, most of the proteins resident in the lumen of the ER are multifunctional, regardless of their Ca²⁺-binding properties. They are involved in maintaining Ca²⁺ homeostasis and they assist in both protein folding and assembly, and lipid synthesis and transport.

Class I Ca²⁺-Binding Proteins in the ER Lumen

The class I ER luminal proteins are those that bind Ca²⁺ with high capacity and low affinity. In most of these proteins, specific regions of the amino acid sequence contain a high proportion of acidic residues, and it is these acidic residues

that are involved in the high-capacity Ca^{2+} binding. The following ER proteins belong to class I: calreticulin, glucose-regulated protein (Grp94), immunoglobulin binding protein (BiP), the protein disulfide isomerase (PDI) family, and calsequestrin.

Calreticulin

Calreticulin (46-kDa) is a major Ca^{2+} storage protein in the ER lumen, which contains both high-affinity/low-capacity and low-affinity/high-capacity Ca^{2+} -binding sites. Specifically, it binds up to 25 mol of Ca^{2+} per mole of protein with $K_d = 1 \text{ mM}$ (low affinity) and 1 mol of Ca^{2+} per mole of protein with a $K_d = 1 \text{ }\mu\text{M}$ (high affinity). Calreticulin, one of the most extensively studied ER luminal proteins, is responsible for binding approximately 50% of the Ca^{2+} stored in the lumen of the ER. As observed for other ER luminal proteins, the expression of calreticulin is upregulated by stress, Ca^{2+} depletion, and metabolic starvation. The over-expression of calreticulin in the ER significantly affects the ER Ca^{2+} storage capacity, Ca^{2+} uptake via SERCA, and release via InsP_3 receptor, indicating an important role for calreticulin in ER Ca^{2+} buffering.

Calreticulin is composed of three structural and functional domains. The N-domain has the most conserved amino acid sequence and binds both Zn^{2+} and adenosine triphosphate (ATP). In conjunction with the central, P-domain of the protein, it enables the chaperone function of calreticulin. The central, P-domain of the protein is very rich in proline residues and contains several repeated amino acid sequences. It forms a highly unusual hairpin-like structure that involves the entire proline-rich region, and it is stabilized by a three-strand anti-parallel B-sheet that is formed by the amino acid repeat sequences. The P-domain binds Ca^{2+} with high affinity and low capacity. It also interacts with other ER chaperones and their substrates. The carboxyl-terminal C-domain of calreticulin contains a large number of acidic amino acid residues, and it is responsible for the high-capacity Ca^{2+} -binding behavior of calreticulin.

In addition to binding and buffering Ca^{2+} in the lumen of ER, calreticulin also plays a significant role as a molecular chaperone with a specificity for glycosylated proteins. Specifically, calreticulin binds N-linked, monoglucosylated carbohydrates on newly synthesized proteins. In conjunction with calnexin, an integral membrane protein and also a chaperone in the ER, calreticulin facilitates protein folding and oligomerization, and it supports quality control in protein folding processes. As components of the calreticulin/calnexin cycle, calreticulin might prefer secretory proteins and calnexin integral membrane proteins. Calreticulin and calnexin both form heterodimeric complexes with ERp57 and other chaperones. The formation of these chaperone-chaperone and chaperone-substrate interactions is regulated by changes in Ca^{2+} concentration in the lumen of the ER.

A deficiency in calreticulin in mice is embryonic lethal at E13.5 due to cardiac malformation with this phenotype rescued by targeted over-expression of calcineurin in the heart. Calreticulin is highly expressed in the heart during embryonic development and significantly downregulated in mature heart. Recent evidence points to a role for calreticulin even early

during embryogenesis, during implantation with high expression from E1 to E4. In addition, embryonic stem cells isolated from calreticulin-deficient mice are unable to form beating cardiomyocytes, but have an increased capacity to differentiate into adipocytes, a lineage that has an inverse relationship to cardiomyocytes. Mouse embryonic fibroblasts deficient in calreticulin have disrupted intracellular Ca^{2+} signaling, partially due to the buffering capacity of calreticulin, but possibly also due to the fact that plasma membrane receptors that are part of the Ca^{2+} signaling pathway are not functional, such as the bradykinin receptor and the thrombin receptor, both G-protein-coupled receptors. The Ca^{2+} signaling capacity of calreticulin, both chaperone function and buffering ability, appears to be critical during embryonic development.

Grp94

Grp94 (94-kDa) is another major Ca^{2+} -binding protein, and one of the most abundant proteins in the lumen of the ER. It binds 8–10 mol of Ca^{2+} per mole of protein with low affinity ($K_d = \sim 600 \text{ }\mu\text{M}$). Like calreticulin, Grp94 contains an acidic C-terminal region that comprises the low-affinity Ca^{2+} -binding site. Because of their relatively high capacity for Ca^{2+} binding and their abundance, Grp94 and calreticulin are the most significant Ca^{2+} -binding/buffering proteins in the ER lumen. The expression of Grp94 is upregulated upon glucose starvation, hence its name (glucose-regulated protein). It binds ATP and requires ATP hydrolysis for chaperone function but binds to limited numbers of nascent proteins, most of them advanced folding intermediates or misfolded proteins that have been previously associated with other chaperones; it has a relatively low affinity for early folding intermediates. The N-terminal portion of Grp94 contains one or more high-affinity Ca^{2+} -binding sites which regulates the peptide binding activity of the chaperone. Grp94 is similar in conformation to cytosolic Hsp90 in the absence of nucleotide. It appears that Grp94 is a chaperone specific for advanced intermediates in protein biosynthesis and that it works downstream of, or in conjunction with, other chaperones. Ca^{2+} binding to Grp94 may play a role in the *in vivo* interactions of the protein with other chaperones and with its substrates.

Grp94 deficiency in mice, similar to calreticulin, is lethal *in utero* at day E7.5 due to failure to develop mesoderm. Grp94-deficient embryonic stem cells are unable to differentiate into cardiac, smooth, or skeletal muscle, but have enhanced adipogenesis, similar to calreticulin which may be due to both the chaperone function of Grp94 and possibly the Ca^{2+} buffering capacity. In fact, Grp94 is responsible for chaperoning insulin growth factor II (IGFII), an important factor that is necessary for muscle differentiation, but perhaps may be providing a substantial amount of Ca^{2+} necessary during differentiation for activation of transcription factors.

BiP

BiP is a 78-kDa ER chaperone that was initially identified to bind immunoglobulin heavy chain binding protein (IgH) in B cells. It is a monomeric protein with two distinct functional domains, an ATP-binding domain and a peptide-binding domain. While it has a relatively low capacity for binding

Ca^{2+} (1–2 mol of Ca^{2+} per mole of protein), it contributes possibly as much as 25% of the total Ca^{2+} storage capacity of the ER, and its elevated expression causes an appreciable increase in ER Ca^{2+} storage capacity. BiP assists in the folding of newly synthesized polypeptides by binding to exposed hydrophobic side chains and subsequently coordinating the formation of their correct tertiary and quaternary structure. BiP binds ATP and has high ATPase activity essential for its chaperone function. Its association with nascent polypeptides is stabilized by the high concentrations of Ca^{2+} in the ER lumen and likely involves Ca^{2+} binding. The expression of BiP is upregulated by a variety of stress conditions, including ER Ca^{2+} depletion. During ER stress resulting from Ca^{2+} depletion, BiP senses misfolded protein accumulation and in combination with three other ER proteins, ATF6, IRE1, and PERK, comprises the unfolded protein response. IRE1, PERK, and ATF6 are activated, followed by downregulation in protein production, upregulation of chaperone production, and activation of ER-associated degradation (ERAD). In addition, BiP performs other functions including as a permeability barrier by physically blocking the translocon pore and ratcheting the nascent protein through the pore.

BiP is highly expressed during embryonic differentiation; however, BiP-deficient embryos that are completely devoid of BiP lead to peri-implantation lethality at E3.5. BiP-deficient blastocysts demonstrate a general proliferation defect and an increase in apoptosis of the iodinated contrast media with an inability to generate ES cells. During early development, BiP activity during ER stress may be necessary for implantation and differentiation with BiP essential for embryonic cell growth and pluripotent cell survival. As BiP performs an essential role in the ER as a molecular chaperone as well as a Ca^{2+} buffering protein, BiP chaperone function may be essential for the processing and secretion of growth factors necessary for differentiation, with the Ca^{2+} buffering function necessary for the activation of transcription factors upregulated during the early stages of implantation and differentiation.

The PDI Family of Proteins

Several members of the PDI family are well characterized. Each is folded similarly to thioredoxin, with a typical sequence of α -helices and β -strands. PDI proteins also contain one or more active sites (typically two), again similar to that of thioredoxin. The main function of the PDI family of proteins is to catalyze the oxidation of disulfide bonds and to isomerize incorrectly formed disulfide bonds in newly synthesized polypeptides. Recent studies indicate that some members of this family (PDI, ERp72, and ERcalcistorin/PDI) also contribute to Ca^{2+} buffering in the ER lumen.

PDI

PDI is a ubiquitously expressed multifunctional protein found in the ER. It comprises approximately 0.8% of total cellular protein and attains near millimolar concentrations in the ER lumen of some tissues. During protein folding, PDI catalyzes the formation of native disulfide bonds and disulfide bond rearrangement. PDI is a 58-kDa Ca^{2+} -binding chaperone that binds 19 mol of Ca^{2+} per mol of protein with low affinity ($K_d=2\text{--}5\text{ mM}$). The C-terminus of the protein contains

numerous pairs of acidic residues that form the low affinity, high capacity Ca^{2+} binding sites. PDI is an abundant and versatile redox enzyme that has oxidase, reductase and isomerase activity and interacts with a variety of substrates and is widely distributed in the ER lumen. Its major function is to catalyze disulfide bond formation in newly synthesized proteins and, importantly, high concentrations of Ca^{2+} augment this activity. PDI contains a typical thioredoxin active site, which contains two cysteines separated by two other amino acid residues (the CXXC motif). PDI also functions as a molecular chaperone by binding polypeptides and preventing protein aggregation, and the combination of its redox and chaperone activities is what makes PDI an effective and important enzyme in oxidative protein folding.

PDI knockdown using small-interfering RNA (siRNA) determined that PDI has a protective effect on endothelial cells under both normoxia and hypoxia conditions. To date, no one has been able to generate a PDI-deficient mouse model, possibly due to the critical role of PDI during cell growth, proliferation, and differentiation.

ERp72

ERp72 is a 72-kDa member of the PDI family that binds 12 mol of Ca^{2+} per mol protein with low affinity. Its amino acid sequence includes an acidic C-terminus that is involved in the high-capacity Ca^{2+} binding. ERp72 contains three thioredoxin-like active sites and has PDI-like activity. The expression of ERp72 is induced under stress conditions, including ER Ca^{2+} depletion. A mouse deficient in ERp72 has not to date been generated.

ERcalcistorin/PDI

ERcalcistorin/PDI, a 58-kDa protein, also has high Ca^{2+} -binding capacity and low affinity. ERcalcistorin/PDI binds 23 mol of Ca^{2+} per mole of protein with low affinity ($K_d\sim 1\text{ mM}$). Like other class I ER Ca^{2+} -binding proteins, the high-capacity Ca^{2+} -binding sites in ERcalcistorin/PDI are localized to a C-terminal stretch of acidic amino acid residues. As noted previously for members of the PDI family, high concentrations of Ca^{2+} augment the protein's isomerase activity. ERcalcistorin/PDI has 55% amino acid sequence identity to PDI, and it shows PDI-like chaperone activity.

Other PDI family members

The PDI family of oxidoreductases contains at least 17 family members and are localized to the ER of mammalian cells. They are thought to catalyze disulfide formation to aid folding or to regulate protein function; however, little is known about their individual functions. While information regarding their Ca^{2+} -binding properties is limited, it has been established that they play a role in protein folding and posttranslational modification. P5, a 44-kDa polypeptide also known as CaBP1, contains two internal thioredoxin-like domains and a C-terminal KDEL retention/retrieval signal. While it does bind Ca^{2+} , it is unclear what role it plays in Ca^{2+} buffering in the ER lumen. Protein disulfide isomerase-related (PDIR) has the three CXXC motifs typically found in proteins within the PDI superfamily that are responsible for their oxidoreductase activity. PDIR is preferentially expressed in cells that actively secrete proteins, and its expression is stress-inducible. PDip is a PDI-like protein

expressed specifically in the pancreas. ERdj5 is an ER localized oxidoreductase expressed in salivary glands. Mice deficient in ERdj5 are viable and healthy but have accelerated ER stress response in the salivary gland. Protein disulfide isomerase-like, testis expressed (PDILT) is a testis-specific PDI with a nonconventional SXXC active motif that participates in disulfide-dependent interactions in the ER. EndoPDI is preferentially expressed in endothelial cells and contains three thioredoxin-fold domains. Erp19 contains a CXXC active site and exists as a dimer. Interestingly, Erp44 and Erp28/29, two other ER localized proteins of the PDI family, each contains a single thioredoxin-fold domain but no thioredoxin-like CXXC active site and may be involved in the processing of secretory proteins within the ER. Each PDI family member appears to have specific substrates that they target and this may help explain the apparent redundancy within the family.

Erp57 and Erp44

Two PDI-like proteins, Erp57 and Erp44, are also involved in the regulation of intraluminal Ca^{2+} homeostasis via an interaction with the Ca^{2+} pump SERCA2b and Ca^{2+} channel InsP3R located in the ER membrane. Both proteins appear to be regulated via an interaction of a PDI family member with a specific luminal loop containing conserved cysteine residues. Extrinsic expression of Erp57 in conjunction with SERCA2b results in inhibited Ca^{2+} transport across the ER membrane and is regulated in a Ca^{2+} -dependent manner through an interaction with calreticulin. When ER Ca^{2+} concentration is high, SERCA2b recruits calreticulin and Erp57, resulting in a feedback loop inhibition of Ca^{2+} uptake. Erp57, a 57-kDa protein, carries out disulfide bond exchange in conjunction with calreticulin or calnexin. Ca^{2+} binding to this protein has not been investigated. When ER Ca^{2+} concentration is low, Ca^{2+} release through the InsP3R is blocked by the PDI family member Erp44 interacting with the luminal conserved cysteines. It may be that interaction of these Ca^{2+} channels with these two family members is regulated by redox conditions within the ER, and is dependent on ER Ca^{2+} concentration.

Due to the large number of oxidoreductases in the lumen of the ER, it was surprising to note that Erp57 is embryonic lethal at E13.5. Targeted Erp57 deficiency in CD19⁺ cells demonstrate impaired assembly of the major histocompatibility complex class I peptide-loading complex, demonstrating a role for Erp57 in immune response. Similar to other molecular chaperones, Erp57 is highly expressed during the very early stages of embryogenesis, including formation of the blastocyst. Erp57 regulation of Stat3 signaling during these early stages may be responsible for the early lethality observed in Erp57-deficient mice.

Calsequestrin

Calsequestrin is a high-capacity Ca^{2+} -binding protein found in the SR of cardiac and skeletal muscle. It binds 40–50 mol of Ca^{2+} per mole of protein with low affinity ($K_d \sim 1\text{--}2\text{ mM}$). Small quantities of calsequestrin are also present in the ER of smooth muscle and the cerebellum. There are two isoforms of calsequestrin that are encoded by distinct genes: a 55-kDa cardiac form and a 63-kDa skeletal muscle form. These proteins have very similar amino acid sequences with a C-terminal

stretch containing over 100 acidic amino acids that are involved in the high-capacity Ca^{2+} binding. Calsequestrin is localized to the terminal cisternae of the SR, where it acts as a Ca^{2+} buffer. It lowers the concentration of free Ca^{2+} inside the SR, thereby decreasing the concentration gradient against which the Ca^{2+} -ATPase must work as it transports Ca^{2+} from the cytosol back into the SR. During the initiation of muscle contraction, Ca^{2+} is released from the terminal cisternae of the SR into the cytosol via the ryanodine receptor. Calsequestrin, in addition to being a reversible buffering protein, also functions as an intra-SR Ca^{2+} sensor and mediates the activity of the Ca^{2+} channel. Ca^{2+} -induced conformational changes in calsequestrin affect the junctional face of these membrane proteins and this, in turn, regulates the opening and closing of the Ca^{2+} channel. Intraluminal Ca^{2+} exerts a two-way modulation in cardiac muscle: increase in SR Ca^{2+} promotes channel opening and depletion triggers channel closing. Interestingly, the crystal structure of calsequestrin shows that it contains three similar domains that contain a thioredoxin-like region. The thioredoxin-like fold may, therefore, be a common structural feature of ER/SR luminal proteins.

Mice deficient in skeletal calsequestrin are viable but exhibit reduced levels of releasable Ca^{2+} and contractile sensitivity, increased spontaneous mortality and susceptibility to heat- and anesthetic-induced sudden death. Muscle from skeletal calsequestrin-deficient mice demonstrates abnormal sarcomere morphology with disruption in orientation of T-tubules, double the number of mitochondria and double the density of Ca^{2+} release channels. Most interestingly, calsequestrin-deficient muscle is fatigue resistant with 100% higher force generated after 2 min of continuous stimulation as compared to wild-type controls. A mouse model deficient in cardiac calsequestrin is also viable and displays normal cardiac contractility, left-ventricular size, and unchanged electrocardiogram (ECG) parameters, but, with a significantly slower heart rate and under stress conditions, exhibits cardiac arrhythmias. The Ca^{2+} buffering capacity of calsequestrin appears to be an integral part of the contractile apparatus in muscle.

Class I/II Ca^{2+} -Binding Protein in the ER Lumen

Stim1 is an unusual protein in that it is a membrane protein that binds Ca^{2+} within the lumen of the ER but utilizes a noncanonical EF-hand motif, generating a low-affinity (K_d is between 0.2 and 0.6 mM) Ca^{2+} -binding site. Stim1 is therefore neither part of class I Ca^{2+} -binding proteins or class II Ca^{2+} -binding proteins, but somewhere in between, performing an important role during intracellular Ca^{2+} signaling and involved in ER Ca^{2+} store refilling. After the release of ER Ca^{2+} stores into the cytosol, the cell has a recovery mechanism to reduce the cytosolic Ca^{2+} levels and refill the ER Ca^{2+} stores. This recovery involves the SERCA transporter in the ER membrane as well as Ca^{2+} transporters located at the plasma membrane, which are involved in a specific part of this Ca^{2+} refilling, called store operated Ca^{2+} entry (SOCE). SOCE is a system that was identified a number of years ago, but the actual mechanism has only recently been elucidated. SOCE is an example of coordination between Ca^{2+} signals originating from the ER luminal store and the extracellular

media. Simply, upon ER Ca^{2+} release via InsP_3 , an ER membrane protein, Stim1 senses decreased ER luminal Ca^{2+} and transmits this signal to the plasma membrane where it interacts with a membrane protein, Orai1, responsible for influx of Ca^{2+} .

Stim1

Stim1 is a 685-amino acid, type I transmembrane protein, contains two Ca^{2+} -binding EF hands, one putative disulfide linkage, several glycosylation sites, and a sterile alpha motif (SAM) domain in the luminal domain, as well as cytosolic localized coiled-coil domains, and serine-, proline-, and lysine-rich regions. Stim1 contains two EF-hand motifs, one that binds Ca^{2+} and one that is hidden and is not capable of binding Ca^{2+} . Via the EF-hand Ca^{2+} -binding motif, Stim1 appears to be the initial sensor of decreased ER Ca^{2+} levels, leading to increased Stim1 oligomerization and accumulation near the plasma membrane. The K_d of the EF-hand domain of STIM1 is between 0.2 and 0.6 mM, consistent with ER Ca^{2+} level fluctuations. This K_d is more than 10–100-fold higher than the cytosolic EF-hand Ca^{2+} -binding protein, calmodulin, with Stim1 specially designed to sense changes in the relatively high Ca^{2+} concentration of the ER compartment. Ca^{2+} signaling can trigger dynamic changes of the ER with movement of specialized domains of the ER, specifically movement of the transmembrane protein Stim1, involved in sensing luminal Ca^{2+} concentration, to a sub-plasma membrane location where it is in direct contact with a Ca^{2+} pump, Orai1. This interaction stimulates direct Ca^{2+} influx from the extracellular media, leading to increased cytosolic Ca^{2+} levels. Ca^{2+} is taken up into the ER via the SERCA pump and is used to fill the ER Ca^{2+} stores, enabling the cell to be ready for the next round of Ca^{2+} signaling. Release of ER Ca^{2+} does not result in a uniform increase in all areas of the cytosol, but generates areas of high concentration, closely associated with the compact region between the ER and plasma membrane where Ca^{2+} channels on the plasma membrane open, called Ca^{2+} microdomains. The complex of Ca^{2+} signaling proteins in these microdomains may account for the specific characteristics of individual Ca^{2+} signals. It is possible that the ER-plasma membrane punctae containing Stim1 and Orai1 may perhaps produce an SOCE microdomain.

Stim1-deficient mice present with perinatal and early post-natal lethality and growth retardation. Cells isolated from Stim1-deficient mice demonstrate abnormal cellular physiology and decreased platelet aggregation; thapsigargin-induced Ca^{2+} store release is reduced by 60%, with subsequent SOCE almost completely absent. Stim1 is important for ER Ca^{2+} store refilling, a necessary part of intracellular Ca^{2+} signaling.

Class II Ca^{2+} -Binding Proteins in the ER Lumen

Class II Ca^{2+} -binding proteins in the ER lumen are those that bind Ca^{2+} with high affinity ($K_d = 1 \mu\text{M}$ or less). Much less is known about this class of Ca^{2+} -binding proteins, which includes reticulocalbin, Cab45/stromal cell derived factor 4, calumenin, ERC-55/TCBP-49/E6BP, crocalbin/CBP-50, and calreticulin. The structure, function, and Ca^{2+} -binding

properties of calreticulin have been discussed previously with the class I ER proteins. The class II family of proteins are localized in the cytosol, in various parts of the secretory pathway, secreted to the extracellular space or on the cell surface and may play important roles in the secretory pathway. The emerging functions appear to be highly diverse. With the exception of calreticulin, they all contain six or seven EF-hand type, high-affinity Ca^{2+} -binding sites, and they are considered to be members of the reticulocalbin family or CREC family. This family is a new subset of the EF-hand superfamily of proteins. The function of the high-affinity Ca^{2+} -binding sites in these proteins is not clear, but they may be involved in Ca^{2+} -dependent processes. They may also play an important structural role in the proteins.

Reticulocalbin is a 44-kDa protein that contains six EF-hand motifs. The difference between the amino acid sequences of these domains and EF-hand consensus sequences suggests that some of the domains may have lost their Ca^{2+} -binding capability. Cab45 is a 45-kDa, ubiquitously expressed protein. It contains six EF-hand Ca^{2+} -binding motifs. In contrast to reticulocalbin and ERC-55, which are soluble components of the ER, Cab45 is localized to the Golgi. Cab45 is the first Ca^{2+} -binding protein that has been localized to the lumen of the Golgi, a post-ER compartment. Calumenin is a 39-kDa member of the reticulocalbin family. It is highly homologous to other family members, including reticulocalbin, Cab45, and ERC55. It is localized to the lumen of the ER and has a KDEL-like (HDEF) ER retrieval signal. Calumenin is linked to the inhibition of several proteins in the ER or SR membrane, the vitamin K (1) 2,3-epoxide reductase, the gamma-carboxylase, the RyR, and the Ca^{2+} -transporting ATPase, SERCA. Calumenin has also recently been shown to influence the synthesis of certain coagulation factors in conjunction with thrombospondin1. ERC-55 (55-kDa) comprises an amino-terminal signal sequence followed by six copies of the EF-hand Ca^{2+} -binding motif.

Interestingly, none of the class II CREC family members have been used to generate a deficient mouse model system to date, potentially due to the diverse function and expression as well as inherent nature of Ca^{2+} signaling.

The Functional Significance of Ca^{2+} Buffering in the ER

There are many Ca^{2+} -binding proteins in the ER lumen that both bind and buffer Ca^{2+} and that also assist in protein folding and posttranslational modification. Ca^{2+} buffering within the ER lumen is an essential component of proper cellular Ca^{2+} homeostasis. Furthermore, it has a profound effect on other ER functions including protein and lipid synthesis and stress response. For example, reduction of Ca^{2+} concentration in the ER leads to the accumulation of misfolded proteins, increased expression of ER chaperones, and ER to nucleus/ER to plasma membrane signaling, which inhibits protein synthesis and facilitates protein degradation. Overall, disruption of ER Ca^{2+} homeostasis has profound effects on intracellular communication and cell growth, resulting in organellar diseases, and it has detrimental effects at cellular and systemic levels. This is readily demonstrated by the varied but acute phenotypes associated with Ca^{2+} -binding proteins as seen in mouse model systems. These Ca^{2+} buffering

protein-deficient mouse models provide insight into Ca^{2+} signaling regulation and protein function. By targeting a specific gene and therefore protein to be deficient in the mouse and observing the phenotype, researchers can infer probable function. The broader application of these mice may be transmitted into other areas of biomedical research. Ca^{2+} -binding proteins play an important role in the translation, amplification, and prolonging Ca^{2+} signals, performing essential negative and positive feedback roles in Ca^{2+} trafficking and ultimately facilitating cells to generate rapid changes in local Ca^{2+} levels. The Ca^{2+} present in the ER stores serves as a source of easily releasable Ca^{2+} , and is also important as a regulator of a number of ER enzymes and proteins, including feedback regulation of the IP_3R , the RyR , and SERCA . Coordination of ER luminal Ca^{2+} release and extracellular Ca^{2+} influx into the cytosol is critical as sustained cytosolic Ca^{2+} levels are cytotoxic and lead to apoptosis. Overall, it is clear that the ER may be defined as a multifunctional organelle able to detect and integrate incoming signals, modulate its own luminal dynamics,

and generate output signals in response to environmental changes.

Glossary

Ca²⁺ transient A temporary rise in the intracellular levels of free Ca²⁺ (≈ 100 nM to 1 μM) induced by a variety of extracellular signals (hormones, neurotransmitters, and depolarization) that may vary in its localization, duration, frequency, and amplitude.

Hippocampus Part of the limbic system of the brain that is involved in spatial learning; because of its laminar architecture, it is routinely used for electrophysiological studies designed to evaluate synaptic connectivity and plasticity.

Long-term potentiation A long-lasting increase in synaptic strength that could function to strengthen synaptic connectivity; it is considered to represent a cellular correlate of learning and memory.

Morris water maze An apparatus that is routinely used to assess spatial learning and memory in rodents. In this task, a mouse is placed in a large tub of an opaque liquid and assayed both for its ability to find a visible platform as well as a submerged platform – tasks that evaluate the general function and ability to learn the task as well as the mouse's spatial learning, respectively.

Pre- and postsynaptic elements of neurons Components of typical neuronal synapse: the presynaptic terminal releases a neurotransmitter that diffuses across a synaptic cleft to bind and activate ligand-gated channels along the postsynaptic specialization.

Pseudosubstrate A component of the autoregulatory domain that binds to the substrate-binding pocket on the catalytic domain to prevent kinase activity in the absence of calmodulin.

Calcium/calmodulin-dependent protein kinase II (CaMKII) is a multifunctional serine/threonine (Ser/Thr) protein kinase involved with a diverse array of cellular functions. From metabolism and cytoskeletal organization to gene expression and the cell cycle, CaMKII phosphorylation of key substrates transduces a transient rise in free calcium (Ca²⁺) induced by electrical activity, neurotransmitters, hormones, and other signaling molecules into diverse cellular effects. CaMKII is particularly important in the heart and nervous system, where genetics (knockouts, knockins, and transgenics) has been employed to delineate its key functions, including excitation–contraction coupling in heart and learning/memory in brain. In neurons, CaMKII is strategically localized in both pre- and postsynaptic compartments, where it regulates Ca²⁺-dependent processes central to neuronal communication, including neurotransmitter synthesis and release and ion flux through voltage- and ligand-gated channels. In cardiomyocytes, CaMKII functions to tune gene expression and the Ca²⁺ signaling machinery in response to myocyte activity and hormones. CaMKII possesses autoregulatory properties that may enable it to function as a 'molecular switch' to translate the calcium signaling associated with cellular activity into graded levels of kinase activity. Autophosphorylation can be considered as a form of molecular memory, as it generates a form of persistent activity (autonomous) that is temporally uncoupled from the Ca²⁺ signal. This autoregulation also enables CaMKII to function as a Ca²⁺ spike integrator – the ability to generate graded levels of autonomous activity that is differentially sensitive to the frequency of Ca²⁺ transients. These emergent properties underlie its function as a cognitive kinase with both short- and long-term consequences on complex behaviors, such as learning and memory. In heart, this may enable it to decode heart rate and coordinate

physiological changes, such as the 'fight or flight' response, by modulation of many substrates involved in Ca²⁺ signaling and homeostasis.

Neuronal CaMKII: Localization and Substrates

CaMKII is highly concentrated in the nervous system. At roughly 1–2% of the total protein in the brain, it is the predominant Ca²⁺/calmodulin (Ca²⁺/CaM)-regulated kinase in the central nervous system. CaMKII has a diverse intracellular localization, including the postsynaptic density (PSD), a cytoskeletal specialization replete with signaling molecules (e.g., ligand- and voltage-gated receptors, kinases, phosphatases, and anchoring and structural proteins) that lie immediately across the presynaptic terminal below the postsynaptic membrane. Biochemical cascades at the PSD regulated by CaMKII are likely central to the function of this highly specialized signaling network for the following reasons: (1) CaMKII constitutes a significant fraction of the total PSD protein, (2) it is recruited to the PSD in an activity-dependent manner, (3) it anchors to multiple PSD proteins (e.g., densin-180, α-actinin, and N-methyl-D-aspartate (NMDA) receptors), and (4) it regulates the activity of multiple PSD proteins through phosphorylation. One prominent PSD substrate of CaMKII is the GluR1 subunit of the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-subtype of the glutamate receptor. CaMKII phosphorylation of a specific serine (Ser⁸³¹) in this channel increases its conductance by favoring the open probability of its high conductance state. CaMKII also regulates the trafficking and postsynaptic insertion of AMPA receptors. Although both effects could contribute to synaptic

Figure 1 A variety of extracellular signals (e.g., depolarization, neurotransmitters, and hormones) function to elevate intracellular Ca^{2+} levels through the action of ligand- and voltage-gated channels and IP_3 -operated intracellular stores. Activation of CaMKII (α , β , γ , and δ isoforms) throughout the neuron via Ca^{2+} /CaM leads to phosphorylation of substrates at the membrane, cytoskeleton, postsynaptic density (PSD), nucleus, and in the cytosol. Adapted from Hudmon A and Schulman H (2002) Neuronal Ca^{2+} /calmodulin-dependent protein kinase II: The role of structure and autoregulation in cellular function. *Annual Review of Biochemistry* 71: 473–510.

plasticity, the high concentration of CaMKII in the PSD also suggests that this protein plays a structural function at the synapse. For example, CaMKII functions as a scaffold to bind and recruit the ubiquitin proteasome to dendritic spines.

Presynaptic CaMKII regulates neurotransmitter synthesis and neurotransmitter vesicle availability and release by its phosphorylation of vesicle proteins (e.g., Synapsin I) cytoskeletal regulating proteins (e.g., MAP2), membrane channels (e.g., calcium channels), and other enzymes (e.g., tyrosine hydroxylase). CaMKII is also present in the nucleus, where it phosphorylates key substrates (e.g., CREB) involved in the regulation of gene transcription and long-term changes in neuronal function. Thus, CaMKII is strategically positioned throughout the neuron to transduce and coordinate a host of calcium-mobilizing stimuli into the appropriate alterations in neuronal function (see Figure 1).

Activation, Autoregulation, and Structure of CaMKII

CaMKII is composed of a family of highly conserved isoforms (α , β , γ , and δ) that are encoded by unique genes and differentially expressed throughout the body (see Figure 1). Although the δ and γ isoforms are ubiquitous, the α and β isoforms are highly expressed in the nervous system. The molecular weights of these subunits range from 54 to 72 kDa, with α isoform being the smallest subunit at 54 kDa. This size difference is due primarily to domain insertions in the region between the regulatory and association domains (i.e., variable domains) because each of these genes encodes protein products possessing a catalytic, regulatory, and association domain. A prototypical α -subunit of CaMKII, illustrating the relative positions of

these domains, is shown in Figure 2. Like all protein kinases, the catalytic domain serves to bind substrates and catalyze the phosphotransferase reaction from Mg^{2+} /adenosine triphosphate (Mg^{2+} /ATP) to the protein substrate.

CaMKII is coupled to the Ca^{2+} stimulus via CaM, a small dumbbell-shaped protein that, following Ca^{2+} binding, is competent to bind and activate CaMKII and other target proteins. The autoregulatory domain is composed of three components: a region that contains the Thr286 autophosphorylation site, an adjacent domain that anchors the regulatory domain to the catalytic surface, and a C-terminal region that contains the CaM recognition sequence. Autophosphorylation of Thr286 permits CaM to bind into the middle region (presumably to Phe293) to enable high-affinity binding (CaM trapping) of CaM to the autoregulatory domain. The association domain produces the association of kinase subunits into a multimeric complex, termed the 'holoenzyme'.

A computer-assisted reconstruction of α -CaMKII obtained from images using transmission electron microscopy indicated that the catalytic heads extend from the gear-shaped central core in a dodecameric (12 subunits) arrangement (Figure 2). Although the CaMKII holoenzyme has yet to be resolved at the atomic resolution, crystal structures of the catalytic and association domains have been independently resolved. The oligomerization domain functions to bring catalytic subunits within the holoenzyme into close approximation for a trans-autophosphorylation event (Figure 2, lower right). The regulatory domain blocks substrate access to the catalytic surface in the nonactivated state; however, following Ca^{2+} /CaM binding, the regulatory domain "peels" back to expose the catalytic cleft and substrate binding pocket for kinase activity (Figure 2, lower left).

Figure 2 Linear diagram of α -CaMKII illustrating the catalytic, regulatory, and association domains. Like all kinases, the catalytic domain is composed of both an ATP and a protein–substrate binding region. The autoregulatory region is a trifunctional module (shown in green), composed of a region that contains the Thr286 autophosphorylation site, a region that serves to anchor the regulatory domain to the catalytic surface, and a region that contains the calmodulin recognition motif. The association domain drives subunit multimerization into a holoenzyme (orange). A computer-assisted reconstruction of α -CaMKII obtained from images produced using transmission electron microscopy indicates a dodecameric structure, with 12 catalytic heads radiating out from the top and bottom hexameric rings of association domains (orange) at the center. The crystal structure of a single catalytic subunit (1–315) shows the autoinhibitory domain (green) positioned across the catalytic surface (gold). Adapted from Kolodziej SJ, Hudmon A, Waxham MN, and Stoops JK (2000) Three-dimensional reconstructions of calcium/calmodulin-dependent (CaM) kinase II and truncated CaM kinase II reveal a unique organization for its structural core and functional domains. *Journal of Biological Chemistry* 275: 14354–14359; and from Rosenberg RS, Deindl S, Sung R-J, Nairn AC, and Kuriyan J (2005) Structure of the autoinhibited kinase domain of CaMKII and SAXS analysis of the holoenzyme. *Cell* 123, 849–860.

The isoform composition of the holoenzyme may endow CaMKII with the properties and regulation unique to each isoform. For example, the β isoform possesses an F-actin binding domain that targets this isoform to cytoskeletal structures, where it participates in regulating the sprouting and stability of neuronal dendrites.

The Structure/Function of CaMKII Autophosphorylation

In addition to phosphorylating protein substrates throughout the cell (Figure 1), CaMKII is a substrate for its own catalytic activity via autophosphorylation. Following Ca^{2+} /CaM activation, autophosphorylation may occur at Thr²⁸⁶ (Thr²⁸⁷ of the β , γ , and δ isoforms), at the N-terminal end of the regulatory domain (see Figure 2). Autophosphorylation at Thr²⁸⁶ is not necessary for enzyme activation. Unlike many protein kinases, the ‘activation loop’ of CaMKII requires no phosphorylation for catalytic competence. The autophosphorylation reaction is dominated by an intraholoenzyme intersubunit reaction that requires CaM bound to the subunit acting as kinase as well as the subunit behaving as substrate (Figure 3). Three functional

consequences associated with Thr²⁸⁶ autophosphorylation are: (1) the generation of autonomous activity, (2) an increase in the binding affinity of CaM (CaM trapping), and (3) exposure of a site on the catalytic domain that functions as a binding site to anchor CaMKII to its substrates.

Autonomous Activity

Autonomous activity (Ca^{2+} /CaM-independent activity) has intrigued neurobiologists and enzymologists since its discovery 25 years ago in the marine mollusk, *Aplysia californica* – a well-characterized animal model for studying the molecular mechanisms of learning and memory. Autonomous activity is the residual activity of the autophosphorylated subunit after CaM dissociation. At the structural level, the mechanism of autonomous activity is likely attributed to the negative charges associated with phospho-Thr²⁸⁶ preventing reassociation and inactivation of the catalytic domain by the autoregulatory domain, following CaM dissociation. As indicated below, oxidation of two methionine residues near this critical Thr residue similarly generate autonomous activity.

Figure 3 Autophosphorylation requires coincident Ca^{2+} /CaM binding between neighboring subunits within CaMKII. Catalytic/regulatory regions are depicted from subunits within the same holoenzyme (i.e., intraholoenzyme) and CaM is depicted as the purple dumbbell. Ca^{2+} /CaM binding displaces the autoinhibitory domain to activate subunits within the holoenzyme. Coincident binding of Ca^{2+} /CaM exposes the autonomy site (Thr²⁸⁶), represented as a dashed circle, of one subunit for phosphorylation by an active neighboring subunit in an intersubunit reaction. Adapted from Hudmon A and Schulman H (2002) Neuronal Ca^{2+} /calmodulin-dependent protein kinase II: The role of structure and autoregulation in cellular function. *Annual Review of Biochemistry* 71: 473–510.

CaM Trapping

Among the various CaM target proteins reported, CaMKII possesses a relatively low binding affinity for CaM ($K_d \sim 15$ nM). However, following autophosphorylation, the CaM binding affinity is increased by over a 1000-fold ($K_d \sim 20$ pM), thus attaining one of the highest CaM binding affinities. The autophosphorylation of Thr²⁸⁶ is thought to indirectly produce CaM trapping because a peptide designed from the Ca^{2+} /CaM-binding domain of CaMKII (290–309) possesses high-affinity Ca^{2+} /CaM binding, even though Thr²⁸⁶ is not contained within the peptide sequence (see Figure 2). This is mechanistically consistent with steric constraints or an inaccessibility of the binding site for Ca^{2+} /CaM in the non-Thr²⁸⁶ autophosphorylated state. In neurons, autophosphorylation and subsequent CaM trapping appear to regulate the translocation and dissociation of CaMKII from the PSD. Priming or prior neuronal stimulation is believed to enhance CaMKII autophosphorylation, a process that may trigger long-term PSD association.

Substrate Anchoring

The subcellular targeting of multifunctional kinases (e.g., CaMKII, cyclic adenosine monophosphate (cAMP)-dependent protein kinase, and protein kinase C) is thought to be integral

to substrate specificity and the kinetics of the phosphorylation reaction. Ca^{2+} /CaM binding and autophosphorylation of Thr²⁸⁶ expose a binding site on CaMKII to permit anchor proteins and substrates to directly associate with the enzyme. Protein targeting may also afford new modes of CaMKII regulation. For example, CaMKII targeting to the NR2B subunit of the NMDA-type glutamate receptor requires Ca^{2+} /CaM to induce binding. However, once the interaction is formed, the bound enzyme remains active ‘even’ in the absence of Ca^{2+} /CaM and Thr²⁸⁶ autophosphorylation. Binding of the NR2B subunit to the catalytic domain may act as a wedge to prevent the autoregulatory domain from reforming its contacts subsequent to CaM dissociation. A number of new CaMKII interactors utilizing a similar binding mechanism have been described, including dopamine receptors, connexins, accessory subunits for ion channels, and the proteasome. In addition, autophosphorylation associated with ischemia and epilepsy leads to a new site, Thr²⁵³, which appears to enhance CaMKII interaction with PSD-binding proteins.

Autophosphorylation at Thr³⁰⁵/Thr³⁰⁶

Ca^{2+} /CaM-independent autophosphorylation occurs at amino acids Thr³⁰⁵/Thr³⁰⁶ within the CaM-binding domain. Often referred to as ‘inhibitory autophosphorylation’, it is initiated

once $\text{Ca}^{2+}/\text{CaM}$ dissociates from a kinase phosphorylated at Thr²⁸⁶. Autophosphorylation within the CaM-binding domain (Thr³⁰⁵ or Thr³⁰⁶) blocks rebinding of CaM to this subunit. This autophosphorylation also occurs in the basal state (auto-inhibited), by an intrasubunit mechanism. Basal autophosphorylation preferentially occurs at Thr³⁰⁶, and blocks $\text{Ca}^{2+}/\text{CaM}$ binding. Thus, autophosphorylation is a complex process involving multiple sites that can function to uncouple CaMKII from requiring $\text{Ca}^{2+}/\text{CaM}$ for activity as well as preventing $\text{Ca}^{2+}/\text{CaM}$ from binding to activate (or reactivate) the kinase.

Autophosphorylation as an Index of Neuronal Activity

CaMKII is a major mediator of cellular stimuli related to elevation in intracellular free Ca^{2+} . Autophosphorylation of CaMKII in response to these stimuli not only potentiates its activity beyond the Ca^{2+} transient, but also translates the temporal dynamics (e.g., frequency) of Ca^{2+} signaling. *In vitro*, CaMKII subjected to $\text{Ca}^{2+}/\text{CaM}$ pulsed at varying frequencies generates distinct graded levels of autonomous activity *in vitro*. The level of CaMKII autonomy or level of phospho-Thr²⁸⁶ in response to cell stimuli is commonly

used to monitor its activity. Although the molecular mechanisms of this frequency detection remains to be fully elucidated, factors identified in computer simulations important for this process include the effective cooperativity in the Thr²⁸⁶ autophosphorylation reaction and the availability of CaM for this reaction. In cells, CaM is thought to be largely bound to a variety of cellular proteins and presumably not available to maximally activate all of its targets. CaMKII activation and autophosphorylation are particularly sensitive to limiting CaM levels, as its relatively low affinity for CaM would predict that a transient rise in Ca^{2+} would lead to only a few of the subunits in each holoenzyme being activated (Figure 4). In addition, structural data suggest that cooperativity may also be generated when the catalytic surface of an activated subunit captures the regulatory domain of non-activated subunits to facilitate CaM binding to the captured subunit. This process would potentiate CaM binding and subsequent autophosphorylation of adjacent subunits within the holoenzyme. Because autophosphorylation further prolongs CaM association, a feed-forward process ensues at a threshold level of autophosphorylation to produce the non linear Ca^{2+} spike frequency function for CaMKII activation/autophosphorylation as illustrated in Figure 4.

Figure 4 (Left) The role of coincident CaM binding, autophosphorylation, and CaM trapping in Ca^{2+} spike-frequency detection. Inactive subunits within CaMKII (holoenzymes are shown as 6-mers for simplicity) are represented by open circles. $\text{Ca}^{2+}/\text{CaM}$ (blue circle) binding activates a given subunit (shown in red) and coincident $\text{Ca}^{2+}/\text{CaM}$ binding results in autophosphorylation and CaM trapping ('P' inside a filled dark red circle). During low-frequency Ca^{2+} spikes, CaM completely dissociates between Ca^{2+} spikes, effectively producing 'naïve' CaMKII subunits at each inner spike interval. However, at high Ca^{2+} spike frequencies, CaM does not completely dissociate between Ca^{2+} spikes; this increases the probability that coincident CaM binding, autophosphorylation, and CaM trapping may occur – a process that effectively increases the probability that a neighboring subunit will also bind $\text{Ca}^{2+}/\text{CaM}$ during successive spikes to produce the nonlinear increase in autonomous activity illustrated by a computer simulation encompassing the biophysical and enzymatic characteristics of CaMKII (Right). Adapted from Hudmon A and Schulman H (2002) Structure–function of the multifunctional Ca^{2+} /calmodulin-dependent protein kinase II. *Biochemical Journal* 364: 593–611.

CaMKII in Heart

The cardiac action potential stimulates CaMKII with each heartbeat, which then performs the function of a master regulator of multiple downstream physiological responses across a range of heart rates and timescales. These include Ca^{2+} homeostasis, excitation–contraction coupling, arrhythmia and automaticity, and cardiomyocyte hypertrophy. The kinase is concentrated along the Z band in ventricular myocytes in association with its substrates (L-type Ca^{2+} channel (LTCC) and the ryanodine receptor), where it is poised to regulate Ca^{2+} influx into the cell as well as release from intracellular stores. CaMKII mediates an important feed-forward effect relevant for both normal physiology and pathophysiology. Ca^{2+} entry via the LTCC activates the kinase, which phosphorylates the channel to facilitate subsequent Ca^{2+} current by shifting channel gating to frequent long openings. This frequency-dependent regulation of cardiac contraction functions to enhance blood flow through the heart despite the shorter duration of the cardiac cycle at high heart rates (i.e., force–frequency relationship or the ‘treppe’ effect). This and other actions are consistent with proarrhythmic electrical remodeling in myocardial hypertrophy and heart failure, actions that are enhanced in transgenic animals overexpressing CaMKII and are blocked in transgenic animals expressing a peptide inhibitor of CaMKII.

CaMKII responds to hormonal as well as electrical stimulation of the heart. Paradoxically, the β -adrenergic receptor-mediated stimulation of the heart, which is a classical example of cAMP acting on protein kinase A (PKA) and on a cyclic nucleotide-gated ion channel, also leads to increases in Ca^{2+} and CaMKII activation. In the sinoatrial node that paces heart rate, β -adrenergic stimulation leads to a faster action potential that is the basis of the ‘fight or flight’ response. In mice, this β -adrenergic response is primarily mediated by CaMKII, as it is retained in animals lacking the cyclic nucleotide-gated ion channel and is blocked by inhibition of CaMKII. The pro-oxidant angiotensin II pathway in the heart demonstrates a novel modulation of CaMKII by reactive oxygen species (ROS). ROS leads to oxidation of two methionines Met²⁸¹/Met²⁸² with consequences similar to autophosphorylation of Thr²⁸⁷ of the cardiac CaMKII δ isoform. Oxidation disables the autoinhibitory domain so that the kinase remains active after dissociation of Ca^{2+} /CaM. It usurps a mechanism used by autophosphorylation that links oxidative stress mediated by angiotensin II and ischemia with CaMKII activation and resulting downstream effects, including myocardial apoptosis.

CaMKII in Long-Term Potentiation and Learning and Memory

Neuronal information in the brain is propagated and encoded through synaptic activity, and multiple lines of evidence indicate that CaMKII is critical for long-lasting changes in synaptic efficacy, such as long-term potentiation (LTP). LTP is a long-lasting enhancement in the strength of neurotransmission that is believed to represent a cellular correlate of learning. Synaptic stimulation protocols that produce LTP in the hippocampus also produce long-lasting changes in the activation and autophosphorylation of CaMKII. Importantly, peptide inhibitors of

CaMKII inhibit LTP induction, whereas viral introduction of a constitutively active form of CaMKII occludes LTP generated by the high-frequency stimulation protocols typically used to induce LTP. The activity and autophosphorylation of CaMKII are also important for learning and memory *in vivo*.

Genetic approaches in flies, worms, and mice have greatly advanced our understanding of the molecular mechanisms involved in behavior and learning. Although we will focus on the role of CaMKII in mammalian learning, disrupting the activity of CaMKII induces behavioral or cognitive defects in ‘all’ of these organisms. The genetic deletion in the α -isoform of CaMKII was a pioneering study aimed at understanding the role of CaMKII in mammalian learning and memory. These CaMKII knockout mice displayed deficits in hippocampal LTP and possessed severe learning impairments in spatial learning tasks, such as the Morris water maze. These knockout mice directly implicated CaMKII and hippocampal LTP in mammalian learning and memory.

The use of knockin genetics permitted further dissection of the role of CaMKII in learning by altering autoregulatory properties without ablating kinase activity. A knockin mouse in which Thr²⁸⁶ (α -isoform) was mutated to Ala²⁸⁶ to prevent autophosphorylation displayed deficient LTP and spatial learning, directly implicating Thr²⁸⁶ autophosphorylation in synaptic plasticity and learning. Transgenic mice in which Thr²⁸⁶ was replaced with a charged residue (e.g., Asp²⁸⁶) in order to mimic an autophosphorylated state of the enzyme display enhanced LTP at low levels of transgene expression and deficient LTP at higher levels, suggesting complex interactions between the level of activated CaMKII and its function in regulating synaptic strength. Autophosphorylation within the CaM-binding domain (Thr³⁰⁵/Thr³⁰⁶) has also been implicated in regulating CaMKII targeting and function. Knockin mice that cannot undergo inhibitory autophosphorylation (Ala³⁰⁵/Ala³⁰⁶) have increased levels of CaMKII in the PSD and a lower threshold for LTP. Mimicking inhibitory autophosphorylation (Asp³⁰⁵/Asp³⁰⁶) lowers the CaMKII content in the PSD and blocks LTP induction and hippocampal learning. Finally, disrupting the normal dendritic mRNA targeting of α -CaMKII impairs LTP and learning, suggesting that local translation and delivery of CaMKII to its site of action at the synapse is important for synaptic plasticity learning.

The Tao of CaMKII

The function of CaMKII in synaptic plasticity and learning and memory appears to be tightly linked to its unique structure and autoregulation. The multimeric structure of CaMKII permits different isoforms to associate into a macromolecular signaling complex to provide specific targeting information essential for its subcellular localization as well as an intersubunit autophosphorylation reaction. Key autoregulatory features following autophosphorylation include the ability to: (1) reduce its Ca^{2+} /CaM dependence following dissociation of CaM (autonomous activity), (2) increase its affinity for Ca^{2+} /CaM by over 1000-fold (CaM trapping), (3) enable activity-dependent substrate targeting, and (4) enable it to function as a Ca^{2+} spike frequency detector. Thus, the designation of a kinase as a cognitive kinase (i.e., based on its requirement in learning

and memory) possesses a twofold meaning for CaMKII. Because of this enzyme's complex autoregulation and autophosphorylation, CaMKII activity may directly function as a molecular representation of synaptic activity: a molecular memory that is expressed as a persistent form of activity temporarily uncoupled from the Ca^{2+} stimulus. In brain as in other organs, the role of CaMKII in transducing cellular signals into the complex changes associated with its many functions appears to be an intimate dance between its autoregulation and its capacity to phosphorylate key protein substrates integral to cell function.

Glossary

Autoinhibitory domain (AID) The region of a Ca^{2+} /calmodulin-dependent protein kinase that binds and inhibits the catalytic domain. Inhibition is relieved by interaction with calmodulin and, in some cases, is prevented by subsequent autophosphorylation.

Calmodulin A small cytosolic protein that binds four Ca^{2+} ions and subsequently associates with and modulates many important proteins, including some protein kinases.

Catalytic domain The region of an enzyme responsible for activity; in protein kinases, this domain transfers the γ -phosphate from adenosine triphosphate (ATP) to the target residue.

Protein kinase An enzyme that transfers the terminal (γ) phosphate from ATP to a serine, threonine, or tyrosine residue of a substrate protein.

Protein phosphatase An enzyme that hydrolyzes a phosphate group from a serine, threonine, or tyrosine residue of a phosphoprotein substrate.

The Ca^{2+} /calmodulin-dependent protein kinase enzyme family is activated by increases in intracellular calcium ions (Ca^{2+}) and transfers phosphates from adenosine triphosphate (ATP) to specific serine or threonine residues in other proteins. Family members vary in expression level, subcellular location, and substrate specificity. They are essential for signal transduction in all cells and modulate a variety of physiological processes including learning and memory, metabolism, gene transcription, messenger RNA (mRNA) translation, and muscle contraction.

Ca^{2+} Signaling

Modulation of the concentration of Ca^{2+} is used as an intracellular signal to allow hormones and neurotransmitters to control numerous processes in virtually all cell types. In general, cells have a resting Ca^{2+} concentration of 50–100 nM, but this concentration can spike above 1 μM in an activated cell. Interestingly, these changes in Ca^{2+} concentration can activate extremely disparate signaling cascades not only in different cell types but also in different areas of the same cell. For instance, Ca^{2+} elevation in the nucleus of a neuron activates gene transcription, whereas a similar elevation at the synapse causes neurotransmitter release. These responses are possible because of the hundreds of different molecules that are directly or indirectly responsive to Ca^{2+} , the numerous mechanisms for increasing Ca^{2+} , and the variation in duration, frequency, amplitude, and localization of Ca^{2+} spikes. Ca^{2+} can enter the cell through channels in the membrane or be released from internal stores. The resulting Ca^{2+} spikes can occur on the millisecond level in neurons or be separated by days in the mitotic cell, and can modulate diverse enzymes and/or alterations in the shape of structural molecules. Many of the intracellular effects of Ca^{2+} are mediated by calmodulin, a small protein that undergoes dramatic conformational changes when bound to Ca^{2+} ions. Among the many enzymes

activated by Ca^{2+} /calmodulin (**Figure 1**), members of the Ca^{2+} /calmodulin-dependent protein kinase (CaMK) family mediate diverse physiological responses in most, if not all, cell types.

Protein kinases are enzymes that catalyze the addition of phosphates onto specific serine, threonine, or tyrosine residues in target proteins, thereby regulating them in some way. Substrate proteins include other enzymes, gene transcription factors, scaffolding proteins, receptors, and many other cellular proteins. Thus, kinases can regulate such diverse cellular events as intercellular signaling, cell motility and shape, cell cycle, metabolic pathways, and gene transcription. In addition, kinases themselves may be regulated by intracellular signals, including Ca^{2+} acting via calmodulin. Most cells contain multiple representatives from the diverse family of CaMKs (**Figure 2**). Generally, CaMKs contain an autoinhibitory domain (AID) that interferes with catalysis by blocking or disrupting the catalytic site. This inhibition is relieved by the binding of Ca^{2+} /calmodulin to a domain that overlaps the AID (**Figure 2**), thus activating the kinase.

CaMKs phosphorylate specific serine or threonine residues in substrate proteins based, in part, on the surrounding amino acid sequence. Each of the kinases favors target serines or threonines in specific consensus sequences, although their substrate specificities can overlap. For instance, CaMKII and CaMKIV recognize the consensus sequences $\text{Hyd-X-Arg-NB-X-Ser/Thr-Hyd}$ and $\text{Hyd-X-Arg-X-X-Ser/Thr-X}$ (where Hyd is a hydrophobic residue, NB is a nonbasic residue, and X is any residue), respectively. However, some proteins containing sites that conform to both of these canonical sequences are phosphorylated by the two kinases with similar affinity. In addition, the catalytic domains of most CaMKs contain acidic residues that are important for interaction with the basic residues in their specific substrates (exceptions are noted below). Based on their substrate specificity, CaMKs can be divided into two general groups: those with narrow substrate specificity and those with broad substrate specificity.

Figure 1 Modulation and effects of intracellular Ca^{2+} . Ca^{2+} enters cells via ligand-gated (blue) or voltage-gated (orange) Ca^{2+} channels in the plasma membrane or can be released from sarcoplasmic or endoplasmic reticulum stores via inositol 1,4,5-triphosphate (IP_3) receptors and/or ryanodine receptors (not shown). IP_3 is generated from phosphatidyl-inositol 4,5-bisphosphate (PIP_2) by phospholipase C (PLC), which is activated by ligand binding to specific G_q -protein-coupled receptors (magenta) in the plasma membrane. Cytosolic Ca^{2+} is rapidly extruded from the cell or taken up by the intracellular stores (not shown). The combined actions of these pathways result in spatially localized and transient changes in intracellular Ca^{2+} . The ubiquitous Ca^{2+} -binding protein calmodulin senses the changes in Ca^{2+} and mediates the activation of multiple intracellular enzymes and other processes, including the family of CaMKs.

Figure 2 Schematic representation of CaMK domain structures. The key depicts various domains. The kinase domain of eEF-2K, formerly known as CaMKIII, bears no homology to those of the other CaMKs and thus is represented with white hatching. Most family members have multiple isoforms (not shown).

Narrow-Specificity Ca^{2+} /Calmodulin-Dependent Protein Kinases

Myosin Light Chain Kinase

Myosin is the only known *in vivo* substrate of myosin light chain kinase (MLCK), which is found in all vertebrate muscle cells and many nonmuscle tissues. Distinct genes encode three MLCK isoforms. Skeletal muscle MLCK (SkMLCK) is found

only in skeletal muscle and contains a catalytic core, an AID, a calmodulin-binding domain, and a short N-terminal extension. Cardiac MLCK (cMLCK) is expressed exclusively in the heart, has a structure similar to SkMLCK, and is essential for heart development and proper function. The smooth muscle MLCK (SmMLCK), which is expressed in multiple tissues, also contains an actin-binding domain, a fibronectin domain, a PEVK (region of protein rich in proline, glutamate, valine,

and lysine residues) repeat, and a number of immunoglobulin domains that can be varied by alternative splicing. MLCK is normally activated by Ca^{2+} release from the sarcoplasmic reticulum (SR) or endoplasmic reticulum and phosphorylates the regulatory light chain of the molecular motor myosin II, which is sufficient to initiate contraction in smooth muscle or to potentiate the force and speed of contraction in skeletal and cardiac muscle. Although all forms of MLCK are tightly regulated by calmodulin binding, SmMLCK can be further regulated by phosphorylation. Many kinases, including CaMKII, cyclic AMP-dependent protein kinase (PKA), cyclic GMP-dependent protein kinase, p21-activated kinase, and protein kinase C, can phosphorylate SmMLCK *in vitro* at two serine residues in the calmodulin-binding domain and thus decrease the affinity for calmodulin. In addition, two sites outside the catalytic and regulatory regions of SmMLCK can be phosphorylated by members of the mitogen-activated protein kinase family, resulting in an increase in $V_{\max}$ but no change in K_{CaM} . SmMLCK, but not SkMLCK, is targeted to actin/myosin filaments through interaction with actin subunits.

Phosphorylase Kinase

Phosphorylase kinase (PhK) phosphorylates and activates glycogen phosphorylase, thus accelerating glycogen degradation. Splice variations and gene duplications result in multiple isoforms, many of which are tissue specific. Isoforms of PhK are found in muscle, brain, heart, liver, intestines, and many other cell types. The highly abundant liver and muscle enzymes contribute to blood-glucose homeostasis and provide an energy source to facilitate muscle contraction, respectively. The catalytic γ -subunit associates with α , β , and δ regulatory subunits to form a 1.3-MDa holoenzyme that contains four copies of each subunit. The three regulatory subunits inhibit the phosphotransferase activity of the catalytic subunit. The δ -subunit is in fact calmodulin, which, unusually, is stably associated with the holoenzyme even at low Ca^{2+} concentrations. Ca^{2+} binding to δ partially activates PhK and phosphorylation of the α - and β -subunits by PKA potentiates activation. Binding of additional Ca^{2+} /calmodulin molecules, or Ca^{2+} -bound troponin C, to the holoenzyme maximally activates PhK. In muscle, PhK associates with a protein termed protein targeted to glycogen (PTG), which may facilitate phosphorylation of glycogen phosphorylase *b*, which is also associated with glycogen particles. PhK also interacts with other proteins in a tissue-specific manner, such as tubulin in rat brain lysates, and is found in membrane preparations from various tissue types.

Eukaryotic Elongation Factor 2 Kinase

The ubiquitous 90 kDa eukaryotic elongation factor 2 kinase (eEF-2 K), also known as CaMKIII, phosphorylates Thr-56 in eEF-2, a protein elongation factor that promotes ribosomal translocation along mRNA during translation. Interestingly, the catalytic domain of eEF-2 K bears no homology to conventional kinases and is a member of the α -kinase family. Since eEF-2 is inactivated by Thr-56 phosphorylation, eEF-2 K mediates a global reduction of protein synthesis following Ca^{2+}

elevation. Paradoxically, this global inhibition of protein synthesis can enhance the translation of specific mRNAs that are inefficiently translated under normal conditions. The eEF-2 K contains a calmodulin-binding domain and an eEF-2 recognition domain. Regulation of eEF-2 K is both subtle and complex. In the presence of Ca^{2+} and calmodulin, autophosphorylation of eEF-2 K occurs at several serine residues and confers a partially Ca^{2+} -independent activity. In addition, phosphorylation by a variety of kinases *in vitro* can both up- and downregulate eEF-2 K activity.

Phosphorylation by PKA confers Ca^{2+} independence. Thus, stimulation of β -adrenergic receptors and subsequent cyclic adenosine monophosphate (AMP) elevation causes eEF-2 K activation and inhibition of protein synthesis in cultured mammalian cells. In addition, studies suggest that slight drops in cellular pH (such as those caused by hypoxia and ischemia) cause activation of eEF-2 K. In combination, these data suggest that this kinase may not be a simple, direct link between Ca^{2+} and translation, but rather may function to integrate multiple intracellular signals.

Broad-Specificity Ca^{2+} /Calmodulin-Dependent Protein Kinases

Ca^{2+} /Calmodulin-Dependent Protein Kinase I

Ca^{2+} /calmodulin-dependent protein kinase I (CaMKI) is a ubiquitous cytoplasmic enzyme enriched in brain, liver, and intestine. Three isoforms of the kinase, α , β , and γ , have been reported and are products of separate genes, each of which may be alternatively spliced. CaMKI is an approximately 42 kDa monomer and its catalytic domain shows sequence and structural homologies with those of other serine/threonine kinases. A kinase originally termed CaMKV has been shown to be a splice variant of CaMKI. Goldberg et al. crystallized CaMKI, demonstrating that the AID binds and distorts the ATP-binding pocket in the basal state. Binding of Ca^{2+} /calmodulin presumably disrupts these interactions. A threonine residue in the catalytic domain (activation loop) of CaMKI is then phosphorylated by an upstream kinase, Ca^{2+} /calmodulin-dependent protein kinase kinase (CaMKK), resulting in a 10- to 20-fold increase in CaMKI catalytic activity without conferring Ca^{2+} /calmodulin independence. However, this phosphorylation can occur only when both CaMKK and CaMKI are bound by Ca^{2+} /calmodulin, perhaps permitting synergism in kinase activation. CaMKI phosphorylates synapsin I, cAMP response element binding protein (CREB) *in vitro*, and CaMKI activates the extracellular signal-regulated kinase (ERK) MAP kinase pathway and CREB-dependent gene transcription. A recent study found that CaMKI phosphorylates and regulates the guanine nucleotide exchange factor (GEF) β isoform of the PAK-interacting exchange factor (β PIX) to modulate the F-actin cytoskeleton. The activation of CaMKI was recently shown to enhance growth cone motility and the development of neuronal processes (axons, dendrites, and spines/synapses), in part via its actions on ERK, CREB, and β PIX.

Ca^{2+} /Calmodulin-Dependent Protein Kinase II

CaMKII is a ubiquitous kinase that has been implicated in the regulation of diverse physiological processes, such as gene

transcription, neuronal plasticity, exocytosis, and metabolism. Four separate genes encode the α -, β -, γ -, and δ -isoforms of CaMKII. Each isoform is subjected to alternative mRNA splicing, resulting in over 20 known variants of the kinase, many of which have specific cellular and tissue distributions. In addition to highly conserved catalytic, AID, and calmodulin-binding domains, most CaMKII isoforms contain a C-terminal association domain that facilitates the formation of a dodecameric holoenzyme, and may contain multiple isoforms or splice variants. An X-ray crystal structure of the core of the CaMKII α holoenzyme was recently reported, revealing a stacked pair of hexameric rings. The holoenzyme structure of CaMKII facilitates complex regulatory properties. Each subunit is independently activated by Ca^{2+} /calmodulin binding. When adjacent subunits in a holoenzyme bind Ca^{2+} /calmodulin, there is a trans-autophosphorylation at Thr-286, resulting in Ca^{2+} independence and also a 1000-fold increase in affinity for calmodulin. The kinase can be inactivated only by the actions of cellular protein phosphatases. Additional autophosphorylation at Thr-305 and Thr-306 in the calmodulin-binding domain occurs in the absence of Ca^{2+} /calmodulin. Thr-305/Thr-306 phosphorylation interferes with calmodulin binding, blocking Ca^{2+} /calmodulin-dependent activation. Recently reported X-ray crystal structures of a monomeric catalytic/regulatory domain fragment of CaMKII α provide insights into these dynamic regulatory properties.

The number of subunits in a holoenzyme that become active and autophosphorylated at Thr-286 is related to the frequency and amplitude of Ca^{2+} spikes. This unique capacity to decode complex and dynamic Ca^{2+} signals has been proposed to play an important role in prolonged signaling after transient changes in Ca^{2+} , such as may be involved in learning and memory. Consistent with this idea, transgenic mice in which the CaMKII α gene has been mutated such that the kinase cannot autophosphorylate at Thr-286 or at Thr-305/Thr-306 are deficient in spatial learning tasks.

CaMKII can be found in the cytosol, in the nucleus, and associated with various organelles or membranes, depending on the cell type examined. The identity of CaMKII splice variants expressed is believed to play a role in modulating subcellular localization, although few specific examples have been documented. For example, one variant of CaMKII δ contains a nuclear localization sequence and has been shown to regulate gene transcription in cardiac myocytes. Variable subcellular localization can also be attributed in part to the large number of proteins with which CaMKII may associate, which we have termed CaMKII-associated proteins (CaMKAPs). These include several neuronal proteins (e.g., N-methyl-D-aspartate (NMDA) receptor, α -actinin, synapsin I, and densin-180) and contractile/motor proteins (e.g., F-actin and myosin V). Binding of CaMKII to these proteins may position the kinase close to Ca^{2+} sources, and/or close to specific substrates, and may modulate its availability to cellular phosphatases, thereby affecting the rate of inactivation. However, recent studies suggest that some biological roles of full-length CaMKII isoforms may not require catalytic activity, but may instead depend on the ability to serve as a scaffold to assemble multiprotein complexes, perhaps explaining the very high expression levels of CaMKII in some cells. In this regard, it is interesting that one splice variant of the CaMKII α gene (α KAP) lacks a catalytic domain and functions as a

CaMKAP in muscle by forming hetero-multimers with the conventional isoforms through an intact association domain that are targeted to the SR by a unique N-terminal hydrophobic region.

At last count, CaMKII phosphorylates at least 50 distinct proteins *in vitro* and many of these are likely to be physiologically relevant. However, relatively few of these have been formally shown to be phosphorylated in intact cells under physiologically relevant conditions. One of the best characterized substrates is the neuronal α -amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA)-type glutamate receptor; phosphorylation of this receptor at Ser-831 by CaMKII plays an important role in the regulation of synaptic transmission. CaMKII can also phosphorylate numerous other proteins in neuronal dendrites to regulate excitability, dendritic morphology, and local mRNA translation. In neuronal presynaptic terminals, phosphorylation of synapsin I by CaMKII modulates synaptic vesicle movement. In the heart, CaMKII plays a critical role in feedback regulation of Ca^{2+} dynamics by regulating Ca^{2+} entry via L-type voltage-gated Ca^{2+} channels, by phosphorylating ryanodine receptors to regulate SR Ca^{2+} release, by phosphorylating phospholamban at Thr-17, thereby regulating SR Ca^{2+} uptake via the Ca^{2+} -ATPase, and by phosphorylating histone deacetylase to modulate gene transcription. Recent work has shown that CaMKII inhibition protects cardiomyocytes from developing multiple forms of heart disease.

Ca²⁺/Calmodulin-Dependent Protein Kinase IV

α CaMKIV is a monomeric kinase expressed largely in neuronal tissues, testes, and T cells, whereas the β CaMKIV splice variant is differentially expressed in the cerebellum during development. Like CaMKI, CaMKIV is initially activated by calmodulin binding and is further activated when phosphorylated by CaMKK in its activation loop. However, combined with a subsequent N-terminal autophosphorylation, the activation by CaMKK eventually leads to Ca^{2+} -independent activity of CaMKIV. An additional autophosphorylation at Ser-332 of the calmodulin-binding domain prevents further Ca^{2+} /calmodulin binding in a manner analogous to CaMKII autophosphorylation at Thr-305 and Thr-306. CaMKIV contains a nuclear localization sequence and it is thought to be responsible for Ca^{2+} -dependent phosphorylation of a variety of transcription factors (e.g., CREB, serum response factor, and myocyte enhancer factor 2 (MEF2)) and regulatory factors, such as the CREB-binding protein. In the cytosol, CaMKIV phosphorylates oncoprotein 18, preventing its association with tubulin. Protein phosphatase 2A (PP2A), a ubiquitous multimeric protein phosphatase, associates with CaMKIV in a manner antagonized by Ca^{2+} /CaM, dephosphorylating and deactivating it. This calcium-dependent self-regulating complex may be a prototype for phosphatase-kinase cross-talk in cell signaling. Multiple studies have exploited CaMKIV knockout mice to demonstrate a key role in fear-conditioned memory formation, though recent studies have suggested that other genes may compensate for the loss of CaMKIV in these mice.

Ca²⁺/Calmodulin-Dependent Protein Kinase

CaMKK, originally characterized as an activating factor from brain extracts, can dramatically increase the activity of CaMKI

Figure 3 Modulation of neuronal function by activation of CaMKII and CaMKIV. Glutamate release from presynaptic terminals activates NMDA- (blue) and AMPA- (red) type glutamate receptors on the postsynaptic neuron. The NMDA receptor (NMDAR) is a ligand-gated Ca^{2+} channel. The elevated local intracellular Ca^{2+} in the dendrites activates CaMKII, which phosphorylates AMPA-type glutamate receptors, potentiating synaptic transmission. Ca^{2+} elevation via NMDA- and voltage-gated Ca^{2+} channels (not shown) also signals to the nucleus to activate CaMKK and CaMKIV, driving the transcription of specific genes. The dual CaMKII and CaMKIV signals combine to promote long-term changes in synaptic function. AMPAR, AMPA receptor.

and CaMKIV when incubated in the presence of Ca^{2+} /calmodulin, Mg^{2+} , and ATP. Two isoforms (α and β) of CaMKK have been cloned and their domain organization and function are similar to those of other Ca^{2+} /calmodulin-dependent kinases. However, CaMKK is unique in its method of substrate recognition, lacking acidic residues to recognize basic residues near its preferred phosphorylation sites. Instead, this kinase contains an arginine- and proline-rich (RP) insert that is important for phosphorylation of CaMKI and CaMKIV, and Ca^{2+} /calmodulin must be bound to both CaMKK and the substrate (CaMKI or CaMKIV) for phosphorylation to occur. CaMKK also phosphorylates protein kinase B both *in vitro* and in cultured cells, although this does not require the RP domain, and the AMP-dependent kinase (AMPK), which regulates multiple pathways underlying food intake and metabolic balance in several cell types. Regulation of CaMKK also occurs via other kinases, such as PKA, which phosphorylates CaMKK in its calmodulin-binding domain, resulting in the inhibition of Ca^{2+} /calmodulin-induced activity. Recently, experiments using knockout mice have revealed that CaMKK α plays a role in contextual memory consolidation, while CaMKK β is required for spatial memory consolidation. Surprisingly, these results are true only for male mice, as hippocampal function is unperturbed in female mutants.

Summary

Repetitive transient changes in Ca^{2+} concentration in every mammalian cell are sensed by a number of different Ca^{2+} /calmodulin-dependent protein kinases. Although many of these kinases share a great deal of functional homology, there are diverse regulatory nuances. Moreover, some of these

kinases phosphorylate a number of different substrates, whereas others have only one principal substrate. The specific response of individual cells to changes in intracellular Ca^{2+} concentration likely depends on the subset and specific isoforms of Ca^{2+} /calmodulin-dependent kinases expressed in that cell. For example, in hippocampal neurons, synaptic activity increases Ca^{2+} levels in dendritic regions. In the short term, dendritic Ca^{2+} locally activates CaMKII, which phosphorylates preexisting synaptic glutamate receptors. However, over a longer time frame, Ca^{2+} signals the activation of nuclear CaMKIV and thus the transcription of specific genes. It is the combined actions of CaMKII and CaMKIV that result in long-lasting changes in the synaptic response of these neurons that may underlie learning and memory (Figure 3). However, much work remains to be performed in identifying substrates and physiological roles of the various Ca^{2+} /calmodulin-dependent protein kinases in other cells and tissues.

Glossary

Histone acetyltransferases (HATs) Enzymes that acetylate lysine amino acids on histone proteins by transferring an acetyl group from acetyl CoA.

Histone deacetylases (HDACs) Enzymes that remove acetyl groups from acetylated lysine amino acids on histones.

Protein kinase An enzyme that transfers a phosphate group from adenosine triphosphate (ATP)

to a serine, threonine, or tyrosine residue of a substrate protein.

Protein phosphatase An enzyme that removes a phosphate group from a serine, threonine, or tyrosine residue of a phosphorylated protein substrate.

Transcription factors Proteins that bind directly to sequence-specific DNA regions, thereby controlling the transcriptional activity of their target genes.

Introduction

The control of gene expression has evolved to respond to the environmental and intracellular cues so that cells can adjust their growth patterns and activities, and ultimately make life or death decisions. Cells are exposed to both intrinsic and extrinsic signals in the form of chemical and/or physical factors that are presented to them from either side of the plasma membrane. These signals are converted into intracellular messengers through the actions of receptors, ion channels, and/or effector enzymes. Among these messengers, Ca^{2+} is a central player in many cellular signal-transduction cascades that modulate gene transcription. Due to space limitations, we include only reviews in the field.

Ca^{2+} Homeostasis

The resting concentration of Ca^{2+} in the cytoplasm is normally kept in the range of 10–100 nM. To accomplish this, Ca^{2+} is actively pumped from the cytosol to the extracellular space and into intracellular organelles, mainly the sarco/endoplasmic reticulum (S/ER) and the mitochondria. Ca^{2+} signaling occurs when the cell is stimulated to release Ca^{2+} from intracellular stores and/or when calcium enters the cell through plasma membrane ion channels. Cytosolic Ca^{2+} signals can be evoked by chemical stimuli (hormones, growth factors, and toxins), environmental changes (changes in pH or temperature), mechanical deformation, and depolarization. Elevations of intracellular free Ca^{2+} are generally short-lived (milliseconds to several minutes) due to an elaborated network of calcium buffers, pumps, channels, and exchangers in the plasma membrane, as well as membranes of intracellular Ca^{2+} -storage organelles. As an example, plasma membrane Ca^{2+} -ATPases pump Ca^{2+} from the cytoplasm to the extracellular space, while S/ER Ca^{2+} -ATPases (SERCA) transfer Ca^{2+} from the cytoplasm into the S/ER lumen. In addition, cytosolic Ca^{2+} -binding proteins (e.g., calbindin, parvalbumin, and calretinin) contribute to buffer-free Ca^{2+} , while luminal Ca^{2+} -binding proteins (e.g., calreticulin and calsequestrin) enhance the storage capacity of S/ER for Ca^{2+} .

Different types of Ca^{2+} channels mediate release of Ca^{2+} from intracellular stores, of which inositol(1,4,5)-trisphosphate

receptors (InsP3Rs) and ryanodine receptors (RyRs) are the best characterized. Depletion of Ca^{2+} from the endoplasmic reticulum leads to Ca^{2+} entry from outside the cell by activation of 'store operated channels'. The molecular mechanism involved in the communication between the ER and the plasma membranes has recently been disclosed. At the ER, the STIM1 protein senses the depletion of intracellular Ca^{2+} stores and communicates this state to the plasma membrane. The mechanism involves an orchestrated series of events, including the aggregation into macromolecular complexes with the plasma membrane protein Orai, as well as with other molecules such as the TRPC1 channel, SERCA and the microtubule end tracking protein EB1, to induce activation of Ca^{2+} influx.

Changes in cytosolic-free Ca^{2+} underlie a multitude of basic cellular functions ranging from extremely rapid, such as neurosecretion and skeletal muscle contraction, to delayed responses, such as cellular differentiation and mitogenesis. It is well known that different cell types use various elements from a broad Ca^{2+} signaling 'toolkit' and that the characteristics of the global Ca^{2+} signals, and their physiological effects, can vary considerably. Downstream the Ca^{2+} signal, different signaling cascades, including the Ras/mitogen-activated protein kinase (MAPK) pathway, calcium/calmodulin (CaM)-dependent protein kinases, the phosphatase calcineurin, and Rac GTPases, convey the information to mediate changes in gene expression by stimulating the translocation of transcription factors from the cytosol to the nucleus, by causing the translocation and/or activation of enzymes that regulate the activity of nuclear transcription factors or the structure of chromatin.

The Nuclear Calcium Signal

For many years, it has been accepted that the propagating cytosolic Ca^{2+} wave enters the nucleus through the nuclear pores of the nuclear envelope (NE) by passive diffusion. Although undisputable, this mechanism, however, is not exclusive and recent studies have highlighted the existence of an independent nuclear Ca^{2+} compartment nourished by Ca^{2+} signals generated locally.

Like in the cytosol, a nuclear Ca^{2+} toolkit contributes to the genesis of the nuclear Ca^{2+} signal, though it is still not well understood how the nuclear Ca^{2+} signal is generated in the

nucleoplasm and whether the nuclear signal is autonomous or somehow influenced by cytosolic cues. To date, the most widely implicated mechanism for nuclear Ca^{2+} release is via the activation of InsP3 receptors, which could occur independently of cytosolic messengers by mechanisms parallel to those described at the plasma membrane. Activation of phospholipase C (PLC) enzymes at the nuclear membrane leads to the hydrolysis of the membrane phospholipid phosphatidyl inositol-bisphosphate to form inositol 1,4,5-trisphosphate (IP3) and diacylglycerol (DAG). DAG activates the protein kinase C (PKC) enzyme, while IP3 diffuses to bind to InsP3 receptors and release Ca^{2+} . In the nucleus, InsP3 receptors are present in the NE and trigger Ca^{2+} release from the NE lumen directly into the nucleoplasm. InsP3 receptors are located also in small vesicular Ca^{2+} stores within chromatin, which could represent nuclear InsP3-sensitive Ca^{2+} stores. Other receptors such as RyR and nicotinic acid adenine dinucleotide phosphate receptors are also present in the NE in various cell types and regulate Ca^{2+} signaling in the nucleus.

The mechanism by which nucleoplasmic Ca^{2+} signals decline back to prestimulation levels has not been entirely clarified. It is known, however, that nuclear Ca^{2+} signals persist considerably longer in the nucleoplasm than in the cytosol. Reduced nuclear Ca^{2+} -buffering capacity in comparison to the cytosol and the absence of nuclear Ca^{2+} ATPases could, in part, explain the slower decay of the nuclear Ca^{2+} signal. Nuclear Ca^{2+} transients, nevertheless, appear to be reversed by passive diffusion through nuclear pore complexes and by uptake into the NE by sodium-calcium exchangers expressed on the inner face of the NE.

Nuclear Mediators of Calcium Signaling

Calcium Sensors

Elevation of cytosolic Ca^{2+} is translated into functional changes in cellular activity by specific sensors that bind Ca^{2+} with different affinities in different subcellular compartments. CaM, S-100 proteins, transcriptional repressor downstream regulatory element antagonist modulator (DREAM), and calreticulin, thus, interact with various nuclear targets in a Ca^{2+} -dependent manner to regulate the activity of transcription factors or enzymes that influence chromatin structure to eventually modify gene expression.

CaM is a ubiquitous protein, although constitutively present in the nucleus. Increase in cytosolic Ca^{2+} enhances CaM transport to the nuclear compartment. Binding of Ca^{2+} produces a conformational change in CaM that promotes interactions of the Ca^{2+} /CaM complex to numerous target proteins. The list of CaM effectors includes the CaM-dependent adenylyl cyclases, phosphodiesterases, protein kinases (CaMK), and the protein phosphatase calcineurin. CaM also regulates the activities of the plasma-membrane Ca^{2+} pump, various ion channels, RyR, and isoforms of the InsP3 receptors, as well as the nuclear import and transcriptional activity of transcription factors such as Sox 9 and several basic/helix-loop-helix (bHLH) proteins. CaM, thus, participates in signaling pathways that regulate many crucial processes such as growth, proliferation, and movement.

Calreticulin is a molecular chaperone located in storage compartments that binds Ca^{2+} with low affinity but high capacity. Although predominantly within the ER, it is also present in

the nucleus where it interacts with the DNA-binding domain of several nuclear receptors, including glucocorticoid, androgen, retinoic acid, and vitamin D receptors. As a result of these interactions, calreticulin inhibits nuclear receptor-mediated transcription. In addition, calreticulin mediates Ca^{2+} -dependent nuclear export of glucocorticoid receptors reducing their availability to mediate transcription.

The S100 protein family comprises at least 25 members, forming the largest group of EF-hand-signaling proteins in humans. They are expressed in many tissues; however, each S100 protein is frequently restricted to one particular tissue or cell type. S100 proteins can form homo- and heterodimers and interact with a variety of target proteins usually in a Ca^{2+} -dependent manner. S100 proteins have been reported to modulate the activity of bHLH and p53 transcription factors and are involved in many biological processes such as cell growth and motility, cell-cycle regulation, differentiation, and cell survival.

Protein Kinases

Activation of kinases and phosphatases constitutes the best-described mechanism by which changes in intracellular Ca^{2+} concentration can affect gene expression.

The CaMK kinase (CaMKI, CaMKII, and CaMKIV) family members contain a catalytic domain, an autoregulatory domain, and an overlapping CaM-binding domain. Binding to Ca^{2+} /CaM triggers kinase activity by facilitating a conformational change that removes the autoregulatory domain from the catalytic pocket to enable substrate access. CaMKs are particularly abundant in brain where they play critical roles in neuronal development, plasticity, and behavior. CaMKs have been associated with activity-dependent direct phosphorylation of several transcription factors, including cyclic adenosine monophosphate (cAMP) response element-binding protein (CREB), CREB-binding protein (CBP), and E-twenty six-1 transcription factor (Ets1), as well as with the nuclear translocation of nuclear factor kappa-light-chain-enhancer of activated B cells (NF κ B) and silencing mediator of retinoic acid and thyroid hormone receptors (SMRTs).

PKC family members can be divided into four structurally and functionally distinct subgroups specified by their divergent regulatory domains. The conventional PKC isoforms (α , β I, β II, and γ) are activated by a combination of DAG and phospholipid binding to their conserved region 1 (C1) domains and Ca^{2+} -dependent phospholipid binding to their C2 domains. The novel PKCs (δ , ϵ , η , and θ), the atypical PKCs (ζ , λ /I, and μ) and the PKN subfamily members (PKN1, PKN2, and PKN3) do not depend on Ca^{2+} or diacylglycerol for activation.

Elevated concentrations of intracellular Ca^{2+} activate conventional PKC isoforms, recruiting the enzyme to the inner leaflet of the plasma membrane or the NE within minutes. This process has been associated with changes in gene expression by two different mechanisms. The first involves phosphorylation of kinase of the inhibitory kappa B subunit (I κ B) followed by nuclear translocation of NF κ B which activates cytokine gene expression and T-cell proliferation. The second mechanism relates to increased nuclear activity of histone acetyltransferases (HATs) and has been described in epidermal cells where Ca^{2+} induces epidermal cell differentiation.

Protein Phosphatases

As important as phosphorylation events, Ca^{2+} -dependent dephosphorylation of specific residues in key proteins within a given transcriptional network also induces drastic changes in the activity of the network. Interestingly, activity-dependent phosphorylation and dephosphorylation are, in some occasions, coupled events that act on a particular protein or even on a particular phosphoresidue. In those cases, the specificities of the calcium signal to activate the two events alternatively require a fine-tuning that is not always well understood.

Calcineurin is a Ca^{2+} /CaM-activated serine/threonine phosphatase, with a catalytic A subunit that binds CaM and a regulatory B subunit that binds calcium. Calcineurin conveys cytosolic Ca^{2+} signals to the nucleus, regulating the activity of at least three important transcription pathways involving nuclear factor of activated T-cell (NFAT), CREB, and myocyte enhancer factor-2 (MEF-2) proteins, which control responses in the immune, nervous, and cardiovascular systems. Calcineurin may also regulate with gene expression by changing the concentration of intracellular-free calcium by dephosphorylating phospholamban, the endogenous regulator of the SERCA2a calcium pump, ryanodine receptors, as well as the IP3R1. Calcineurin has a particularly high affinity for Ca^{2+} /CaM and is at least one order of magnitude more sensitive to Ca^{2+} /CaM than is CaMKII. As a consequence, calcineurin responds to sustained, low-amplitude calcium transients, whereas transient, high-amplitude calcium spikes preferentially activate CaMKII.

PP1 (calcium/calcineurin-dependent type 1 serine/threonine protein phosphatase) contains a highly conserved catalytic subunit and one or more regulatory subunits. PP1 activity is modulated by the interaction with auxiliary proteins that target the enzyme to different subcellular compartments, conferring substrate specificity. A subset of these auxiliary proteins are inhibitory proteins that block the catalytic activity of PP1. These include PP1 inhibitors 1 and 2, dopamine and cAMP-regulated phosphoprotein 32kDa (DARPP-32), as well as protein phosphatase 1 nuclear-targeting subunit (PNUTS) and nuclear inhibitor of protein phosphatase 1 (NIPP-1), two inhibitory subunits of PP1 that direct the nuclear targeting and retention of the enzyme, regulating PP1 nuclear activity. Binding to PP1 and inhibition of its activity are regulated by protein kinase A (PKA) phosphorylation, while calcineurin dephosphorylates inhibitor-1 blocking its activity, which results in PP1 activation. A major role of PP1 activity in the nucleus is to dephosphorylate the transcription factor CREB and terminate CREB-dependent gene expression.

Final Effectors of Nuclear Calcium

Transcription Factors

Nuclear factor of activated T-cells

The NFAT family of transcription factors, NFAT1 (NFATp, NFATc2), NFAT2 (NFATc, NFATc1), NFAT3 (NFATc4), NFAT4 (NFATx, NFATc3), and NFAT5 (TonEBP), are proteins that are evolutionary related to the Rel/NF κ B family. Originally characterized in immune cells, it is now known that all isoforms are ubiquitously expressed and appear to have relatively redundant functions. NFATs induce the expression of genes

important in cellular processes such as development, activation of lymphocytes, differentiation of cardiac muscle cells, and cancer progression.

A key rate-limiting event in the activation of NFATs is a rise in intracellular calcium concentrations. Ca^{2+} /CaM activates calcineurin that induces NFAT nuclear translocation and transcriptional activation. NFAT5 does not possess a calcineurin-binding site, and, therefore, is insensitive to calcium and calcineurin.

Phosphorylation by maintenance kinases such as dual-specificity tyrosine phosphorylation-regulated kinase 2 (DYRK2) and casein kinase 1 prevents NFAT nuclear translocation. By contrast, phosphorylation by export kinases such as DYRK1 and glycogen synthase kinase 3 promotes NFAT export from the nucleus (Figure 1). The process as a whole is extremely rapid, giving NFAT proteins the remarkable ability to sense dynamic changes in intracellular Ca^{2+} levels and frequencies of Ca^{2+} oscillations. In addition to phosphorylation, other posttranslational modifications, such as sumoylation and ubiquitination, have been reported to regulate the cytoplasmic-nuclear trafficking of some NFAT family members.

The MEF-2 family

The MEF-2 family of transcription factors (MEF-2 A–D) includes calcium-dependent regulators of cell division, differentiation, and death. MEF2 has been studied most extensively in muscle cells, though MEF2 is also an important calcium-dependent regulator of neuronal and immune cell differentiation and function. Unlike NFAT, MEF2 is constitutively bound to its cognate DNA-binding elements independently of Ca^{2+} . In resting conditions, MEF2 recruits transcriptional repressors, including Cabin1, MEF2-interacting transcriptional repressor, and histone deacetylases (HDACs) to repress gene expression. So far, two different mechanisms have been described by which MEF2 repression can be relieved. First, after Ca^{2+} influx, the co-repressors are removed from MEF2 by binding to activated CaM, and MEF2 binds instead to co-activators (e.g., p300), resulting in the transcription of target genes. Second, phosphorylation of HDACs by CaMK I and IV creates a phosphodomain that binds to 14–3–3 proteins, mediating the shuttling of HDACs from the nucleus to the cytosol, thus freeing MEF2 to be phosphorylated by MAP kinases, which leads to the full transcriptional activity of MEF2. Activation of nonrepressed MEF-2 proteins is also a Ca^{2+} -dependent process, for which two major mechanisms have been proposed. First, as shown in cerebellar neurons, calcium influx triggers activation of MKK6-p38 MAPK resulting in the phosphorylation of Ser-387 located in the transactivation domain of MEF-2 C. Second, the Ca^{2+} /CaM-dependent phosphatase calcineurin activates MEF-2 through a posttranscriptional mechanism that either increases its DNA-binding activity in cerebellar granules or triggers interaction of MEF-2 and NFAT proteins and recruitment of CBP to these complexes in T lymphocytes. Ca^{2+} /CaM-dependent signaling, thus, prevents formation of the MEF-2/HDAC complexes, induces nuclear export of class II HDACs, activates MEF-2-dependent transcription, and, as a result, stimulates cytokine expression, myogenesis, and neuronal survival (Figure 1).

Figure 1 Calcium-modulated transcription factors. Nuclear-cytosolic translocation of NFAT is regulated by calcineurin (CaN), ‘maintenance’ kinases, and ‘export’ kinases. In resting conditions, MEF2 is bound to DNA forming a complex with transcriptional repressors (Repr.), while calmodulin (CaM) promotes removal of repressors and binding of transcriptional activators (Act.) together with CaN. CREB transcriptional activity is regulated by Ca-dependent and cAMP-dependent kinases as well as phosphorylation-independent events.

Nuclear factor kappa-light-chain-enhancer of activated B cells

NFκB is expressed in nearly all cell types and controls the expression of genes involved in a broad range of biological processes such as immune, inflammatory, and stress responses or neuronal survival. NFκB is a transcription factor composed of diverse combinations of p50, RelA/p65, c-Rel, RelB, and p52. NFκB is normally found in the cytoplasm as an heterodimer retained by the interaction with an inhibitory kappa B (IκB) molecule that masks its nuclear localization signal. Activation of the NFκB signaling cascade results in specific IκB hyperphosphorylation by two IκB kinases, IKKα and IKKβ, and subsequent degradation of IκB by the proteasome complex. This releases NFκB, allowing its nuclear translocation. In addition, more recent studies in T lymphocytes and neurons identified CaMKII as an activator of NFκB.

The cAMP response element-binding protein

CREB is a basic leucine zipper (bZIP) transcription factor activated by both cAMP and Ca^{2+} signals. CREB is ubiquitously expressed and regulates the expression of a wide variety of genes. In the nervous system, where it has been most widely studied, CREB is involved in neuronal survival and synaptic plasticity. Several kinases, including PKA, PKC, MAPKs (ERK and p38), CaMK, and CaMKK phosphorylate CREB at Ser-133 in the transactivation domain, known as the kinase-inducible domain (KID). Phospho-KID facilitates recruitment of the co-activators CBP and p300, which enhances CRE-dependent transcription. CBP/p300 activity is as well modulated by several kinases, including CaMKI and the interaction with the Ca^{2+} -responsive transactivator. The Ca^{2+} signal does not need to propagate to the nucleus to induce phosphorylation of Ser133 on CREB; however, an increase in the level of nuclear Ca^{2+} is

required for CREB-mediated gene transcription to occur. This is because additional Ca^{2+} -dependent phosphorylation of CREB and its co-activators is required.

Calcineurin exerts either stimulatory or inhibitory effects on CREB-dependent gene expression in different cellular systems. In cultured rat hippocampal neurons, calcineurin activation of PP1 limits the duration of CREB phosphorylation and, thus, restricts the transcriptional responses of CREB activation. By contrast, inhibition of calcineurin in non-neuronal cells, such as pancreatic islet cells or chromaffin cells, can block CREB-dependent gene expression (Figure 1).

Phosphorylation of CREB is necessary, but not sufficient to stimulate CREB-dependent transcriptional activity. Moreover, different phosphorylation-independent mechanisms regulate CREB activity. CREB-regulated transcription co-activators (Crtcs) also known as transducers of regulated CREB activity (TORC) transducers of regulated CREB activity proteins, mediate calcium- and cAMP-dependent, phosphorylation-independent activation of CREB. Crtc interacts with the bZIP DNA-binding/dimerization domain of CREB enhancing its transcriptional activity. The pathway involves calcineurin and the repressor salt-inducible kinase. Also, in line with the phosphorylation-independent regulation of CREB activity, a Ca^{2+} -dependent interaction between transcriptional repressor DREAM and CREB or phosphoCREB regulates the accessibility of CBP to the KID domain in CREB, and so compromises CRE-dependent transcription.

The downstream regulatory element antagonist modulator

DREAM binds as a tetramer to specific sites in the DNA (DRE sites) and represses transcription of specific genes in a Ca^{2+} -dependent manner. The DRE sequence was defined as the element responsible for basal and induced expression of the

Figure 2 DREAM-mediated transcriptional repression. (a) Basal repression of DREAM target genes after binding of DREAM tetramers to the DRE site. (b) Stimulated derepression of DREAM-mediated repression by different stimuli including: (i) Ca^{2+} , (ii) DREAM phosphorylation, and (iii) the interaction of DREAM with other nucleoproteins such as αCREM . Once DREAM is detached from the DRE site, transcription of a given target gene will proceed driven by the specific combination of enhancers (E) and silencers (S) present in the promoter region. Adapted from Mellström B, Savignac M, Gomez-Villafuertes R, and Naranjo JR (2008) Ca^{2+} -operated transcriptional networks: Molecular mechanisms and *in vivo* models. *Physiological Reviews* 88: 421–449.

prodynorphin gene. More recent studies, however, have shown DRE sites and DREAM regulation of other targets including a number of immediate early transcription factors such as c-fos, c-jun, and ICER. Furthermore, binding of DREAM to DNA is regulated also by phosphorylation through PI3K and interaction with other nucleoproteins such as phosphoCREM, while the interaction with CREB or TTF-1 allows DREAM to regulate the transcription independently of DRE sites (Figure 2).

The bHLH family

The bHLH superfamily of transcription factors (that include MyoD, Myf5, and myogenin, among others) is essential for numerous developmental processes, including neurogenesis, hematopoiesis, and myogenesis as well as tumor cell invasion and metastasis. Based on tissue distribution, dimerization capacities, and DNA-binding specificities, bHLH proteins have been subdivided into seven classes. In general, bHLH proteins form homo- or heterodimers through the HLH domain and bind to regulatory E-box sequences in the DNA. Upon binding to DNA, most class I, II, and III bHLH dimers activate transcription through the recruitment of cofactors containing HAT activity, such as CBP/p300, p300/CBP-associated factor (PCAF) or the interaction with chromatin-remodeling factors of the mating-type switching and sucrose non-fermenting chromatin remodeler complexes (SWI-SNF) class. Conversely, transcriptional repression by bHLH proteins is related to the capacity to recruit nuclear complexes containing HDAC activity or to block HAT activity.

The regulation of bHLH proteins occurs at many levels, including differential oligomerization and DNA-binding specificities, interaction with negatively acting HLH proteins, phosphorylation, and other posttranslational modifications. Ca^{2+} /CaM regulates DNA-binding activity of bHLH proteins

by interacting with their DNA-binding domains or interfering with PKC-mediated phosphorylation. Moreover, binding of Ca^{2+} /CaM or S100 proteins to bHLH proteins may disrupt their interactions with components of the transcriptional machinery.

The calcium channel-associated transcriptional regulator

Cleavage of the COOH-terminal end of voltage-gated calcium channels (VGCCs) is a well-known phenomenon, and cleaved fragments have been implicated in regulating channel activity by reducing Ca^{2+} influx. Interestingly, the COOH-terminal intracellular fragment of the Cav1.2 subunit of the L-type VGCC, named calcium channel-associated transcriptional regulator (CCAT), was shown to localize in the nuclei of GABAergic inhibitory interneurons in the cortex and hippocampus and to regulate transcription of selective target genes (GABA, gamma aminobutyric acid). Importantly, the nuclear pool of CCAT is rapidly extruded in response to calcium entry following neuronal membrane depolarization. Transcriptional regulation by CCAT does not seem to involve direct interaction with DNA but rather involves interaction with other nucleoproteins, such as p54(nrb)/NonO, nuclear RNA- and DNA-binding protein of 54 kDa, also known as non-POU domain-containing octamer-binding protein.

Ca^{2+} -Dependent Changes in Chromatin Structure

Ca^{2+} -dependent enzymes not only modify the activity of specific transcriptional networks but also act on chromatin-associated proteins, histones (H) and high-mobility group (HMG) proteins, to evoke selective modifications in the nucleosome. The spatial relationship between DNA and the histone core of the nucleosome determines the accessibility of

transcription factors to the DNA and the transcriptional status of surrounding genes. The spatial association between DNA and histones is largely governed by posttranslational modifications of histones, such as acetylation, phosphorylation, methylation, and adenosine diphosphate-ribosylation.

Acetylation and deacetylation, linked predominantly to activation and repression, respectively, are to date probably the most extensively studied posttranslational histone modifications. Histone acetylation is regulated by a balance between HAT and HDAC activities. Several mechanisms are known to regulate these enzymes, including changes in subcellular localization, ubiquitylation-mediated degradation, changes in interactions with regulatory partners or cofactors, and Ca^{2+} /CaM- and CaMK-dependent phosphorylation.

Phosphorylation is a well-characterized posttranslational modification that induces activity-dependent changes in chromatin structure. Ca^{2+} increase induces the specific phosphorylation of histone H3, but not other histones, and of HMG protein-17 allowing gene transcription. Several Ca^{2+} -dependent kinases phosphorylate histone H3 and specific transcription factors to coordinately activate transcriptional networks. The system is reset by PP1, which has been implicated in H3 dephosphorylation.

Concluding Remarks

Recent years have witnessed an eruption of new calcium-sensitive proteins and calcium-dependent pathways that regulate gene expression and cellular activity. Remarkably, a significant progress has been made in unraveling Ca^{2+} -signaling systems in the nucleus. Yet, mechanisms that regulate Ca^{2+} release from nuclear pools as well as Ca^{2+} passage and regulation of nuclear pore complexes are open fields that require further investigation.

Glossary

Calcium-modulated protein Calcium-binding protein found in the cytosol whose structure changes with binding and release of Ca^{2+} ions associated with a pulse of messenger calcium.

Calmodulin Protein consisting of two pairs of EF-hands. It is found in nearly all cells of all eukaryotes and interacts with over 40 different target enzymes or structural proteins.

Chimera Monomeric protein, consisting of two, or more, domain families.

Congruence Two (or more) subfamilies, each having two or more homologous domains, are congruent if the common precursor to all of these subfamilies had the full complement of domains and all of the subfamilies are

related by duplication of entire, encoding gene. Congruent proteins (subfamilies) are characterized by having all their domains 1 more similar to one another than to other domains within the same proteins; correspondingly all domains 2, etc.

EF-hand Protein domain of 30 residues (amino acids) consisting of an α -helix (E), a loop around a Ca^{2+} ion, and a second α -helix (F).

Ortholog Two homologous domains are orthologs if they were generated by speciation of an ancestral organism. If the two domains, in the same or in different species, are related by gene duplication, they are paralogs.

Transduction Process of changing energy and/or information from one modality to another.

Introduction

Many different proteins – extracellular, membrane, and intracellular – bind calcium, more or less selectively. Those calcium-binding proteins in the cytosol or bound to membranes facing the cytosol are inferred to be calcium modulated. That is, when the cell is quiescent, the concentration of the free Ca^{2+} ion is less than 10^{-7} M ($\text{pCa} > 7$) and the calcium-modulated protein is in the apo- or magnesi-form. Following stimulus, the concentration of calcium rises ($\text{pCa} < 5.5$) and the protein binds calcium. The attendant change in structure is involved in the transduction of the information of a pulse or wave of Ca^{2+} ions to an ultimate target enzyme or structure. Most of these calcium-modulated proteins contain from two to 12 copies of the EF-hand domain. There are other proteins in the cytosol that bind calcium and appear to be modulated by calcium; these include proteins that contain one or several C2 domains, such as protein kinases C or synaptotagmin, the annexins, as well as calcium pumps and channels.

Calcium Coordination

Many of the functional characteristics of calcium and of calcium-modulated proteins can be rationalized from the geometry of calcium coordination.

Pentagonal Bipyramid

In proteins, the Ca^{2+} ion (atomic radius 0.99 Å) is usually coordinated by seven oxygen atoms in an approximate pentagonal bipyramidal conformation at average Ca–O distance 2.3 ± 0.3 Å; the oxygen atoms have some lateral flexibility. The Mg^{2+} ion (atomic radius 0.65 Å) is usually bound by six oxygen atoms at the vertices of an octahedron with Mg–O

distance 2.0 Å; these oxygens are in close van der Waals contact with one another. Although many small molecules bind magnesium with greater affinity than they bind calcium, most intra- and extra-cellular proteins bind calcium with much greater affinity than they bind magnesium.

Kinetics of Calcium and Magnesium Binding

The dissociation constant is the ratio of the off rate to the on rate: $K_d(\text{M}) = k_{\text{off}}(\text{s}^{-1})/k_{\text{on}}(\text{M}^{-1}\text{s}^{-1})$. The rate limiting dehydration of $\text{Ca}(\text{H}_2\text{O})_7^{2+}$ is fast, $\sim 10^{8.0} \text{ s}^{-1}$; while that of $\text{Mg}(\text{H}_2\text{O})_6^{2+}$ is slow, $\sim 10^{4.6} \text{ s}^{-1}$. This difference reflects the loose pentagonal bipyramidal versus the tight octahedral packing of the oxygen ligands. The cation must be (partially) dehydrated before it can bind to the protein. These rates are important for modeling the flux of Ca^{2+} ions through the cytosol and the attendant binding of proteins. The increase in affinity of most proteins for calcium relative to magnesium derives primarily from this difference in k_{on} .

Temporal Buffering

It is intriguing that most EF-hand proteins bind calcium $\sim 10,000$ times more strongly than they bind magnesium. This reflects strong evolutionary selection. The cytosolic concentration of the free Ca^{2+} ion is $\sim 10^{-7.2}$ M and that of the Mg^{2+} ion is $\sim 10^{-2.8}$ M; by contrast, both pCa_{out} and pMg_{out} are ~ 2.8 . This means that a cytosolic protein, such as parvalbumin, that binds calcium with high affinity, for example, $\text{p}K_d(\text{Ca}) \sim 8.0$ will also bind magnesium with medium affinity, for example, $\text{p}K_d(\text{Mg}) \sim 4.1$. In the resting cell, it will be primarily in the magnesi-state. By contrast, lower-affinity sites, such as EF-hands 1 and 2 of troponin C have lower affinities for both divalent cations, $\text{p}K_d(\text{Ca}) \sim 6.5$ and $\text{p}K_d(\text{Mg}) \sim 2.3$,

and are apo in the resting state. This leads to the counter intuitive situation in which a pulse of messenger calcium first binds to the weaker apo-sites in domains 1 and 2 of troponin C, misleadingly referred to as calcium specific. The Ca^{2+} ion, whose concentration during the pulse exceeds 10^{-6} M, can bind to the higher-affinity parvalbumin only after the Mg^{2+} ion diffuses off its strong sites. Parvalbumin, with higher affinity for divalent cations, binds calcium after the weaker troponin C and thereby helps to relax the muscle and prevent tetany. Such temporal buffering surely plays a significant role in the propagation and transduction of calcium waves observed in many types of cell types. The information encoded in the frequencies, durations, and amplitudes of calcium waves and spikes might be decoded by a corresponding matching of k_{off} and k_{on} rates for calcium and for magnesium in calcium-modulated proteins.

EF-Hand Containing Proteins

The structure of the EF-hand provides insight into its evolution and function.

Structure of the EF-Hand

The canonical EF-hand (**Figure 1**) consists of α -helix E (forefinger, residues 1–10), a loop around the Ca^{2+} ion (clenched middle finger, 10–21), and α -helix F (thumb, 19–29). Residue 1 is often Glu; the insides of the helices (palmer surfaces) usually have hydrophobic residues that contact the insides of

the other EF-hand of the pair (**Figure 2**). The side chains of the five residues, approximating the vertices of an octahedron (X, residue 10; Y, 12; Z, 14; –X, 18; and –Z, 21), provide oxygen atoms to coordinate the Ca^{2+} ion; residue 16 at –Y bonds to calcium with its carbonyl oxygen. The positions of these ligands within the loop are often referred to as 1, 3, 5, 7, 9, and 12. The Ca^{2+} ion is actually seven coordinate in a pentagonal bipyramid with major axis: X, –X. There are five oxygen atoms in the Y,Z plane since the –Z ligand (residue 21, usually Glu) coordinates Ca^{2+} with both oxygen atoms of its carboxylate group. A Gly at 15 permits a tight bend; residue 17 has a hydrophobic side chain that attaches the loop to the hydrophobic core of the pair of EF-hands.

Several variations to this canonical calcium coordination scheme have been inferred from amino acid sequences and confirmed in crystal structures of other EF-hand proteins. Nearly one-third of all known EF-hands do not bind calcium; those with no indels (insertions or deletions) have a nonoxygen containing side chain substituted at position 10, 12, 14, 18, or 21. Other EF-hands have indels, most notable is EF-hand 1 of the S-100 group subfamilies (**Table 1**), in which several carbonyl oxygens, instead of oxygens of side chains, coordinate the Ca^{2+} ion.

Evolution of the EF-Hand Family

All members of a protein homolog family are inferred to have evolved from a common precursor domain in a single ancestral

Figure 1 The canonical EF-hand. (a) The spheres represent α -carbons. Residues 2, 5, 6, and 9 of helix E and residues 22, 25, 26, and (often 29) of helix F are usually hydrophobic and face the hydrophobic surface of the other EF-hand of the pair. Five residues – 10 (X), 12 (Y), 14(Z), 18 (–X), and 21 (–Z) – coordinate the Ca^{2+} ion and an oxygen atom from a side chain. Residue 21 is usually Glu and contributes both oxygens of its carboxylate to the pentagonal bipyramid coordination of calcium. Residue 16 (–Y) coordinates with its carbonyl oxygen. (b) Helix E, the loop around the Ca^{2+} ion, and helix F are represented by the forefinger, clenched middle finger, and thumb.

Figure 2 Conformations of pairs of EF-hands. Calmodulin consists of two pairs (1 and 2 and 3 and 4) of EF-hands. A flexible tether, eight residues long, connects helix F2 to helix E3. In the crystal structure, F2, the tether, and E3 form a single continuous helix. Calmodulin is widely distributed and interacts with at least 30 different target proteins. Furthermore, the four EF-hands of calmodulin are all canonical; hence, it serves as a reference point for many evaluations and comparisons. (a) The backbone of the pair calmodulin 3 and 4 in its dicalci-form is shown as a cylinder where it is α -helical and as a strand elsewhere. It is viewed down its approximate twofold axis and is shown in light salmon color; the calcium-binding loops are far from the viewer. Dicalci-parvalbumin CD and EF (CD, yellow; linker, light blue; EF green) is superimposed on dicalci-calmodulin 3 and 4; their conformations are very similar. (b) Apo-calmodulin 3 and 4 (yellow, blue, green) is superimposed on dicalci-calmodulin 3 and 4 (salmon); the binding of calcium opens the cleft between the two helices of each EF-hand and between the two EF-hands of the pair. This is a necessary step permitting calmodulin to interact with its numerous targets. (c) Dicalci-calmodulin 3 and 4 (yellow, blue, green) as complexed with the target peptide from myosin light chain kinase (not shown) is superimposed on dicalci-calmodulin 3 and 4 (salmon). Both the 3 and 4 and the 1 and 2 pairs of calmodulin undergo little additional change in conformation to bind their targets. The binding of calcium facilitates binding of calcium and vice versa. Courtesy of Hiroshi Kawasaki, Yokohama City University, Yokohama, Japan.

organism. The most parsimonious interpretation is that all of the EF-hand domains listed in [Table 1](#) are homologs; however, the statistics of sequence alignment are weak since the domains are only 30 residues long. We employ additional criteria, such as the fact that nearly all EF-hand proteins occur in pairs, so-called EF-lobe ([Figure 2](#)), and that in most EF-hand proteins at least one of the two EF-hands binds calcium. Many (portions of) domains have been suggested to resemble the EF-hand. They are not included in [Table 1](#) unless they have passed a hidden Markov model test based on unambiguous EF-hands of known structure. Most EF-hand-containing proteins have been found in eukaryotes; however, there are several examples in eubacteria and viruses. EF-hand proteins, for example, calmodulin, have been found in all eukaryotes subject to thorough investigation. This distribution might reflect an origin in the bacterium that gave rise to eukaryotic cells; other bacteria may have lost their EF-hands. Or, the precursor EF-hand may have arisen in an early eukaryote and its encoding gene transferred to a few bacteria by some sort of transduction or transformation.

Distribution of EF-Hand Domains

EF-hand proteins contain two to 12 tandem copies of the EF-hand domain. EF-hands occur in pairs, EF-lobe, and are related by an approximate twofold axis of rotation ([Figure 2](#)). Although about one-third of all EF-hands are known or inferred not to bind calcium, usually at least one EF-hand domain in any protein does bind calcium with $pK_a(\text{Ca}) \sim 7.0$. The proteins, such as the ubiquitous and archetypical calmodulin, are in the apo- and/or magnesi-form prior to simulation of the cell; following a rise in $[\text{Ca}^{2+}]_{\text{cytosol}}$, the competent EF-hand(s) binds calcium with attendant change in relative orientation of its helices E and F as well as a change in the relationship of the two EF-hands of the EF-lobe. If the protein is chimeric with a non-EF-hand catalytic domain(s), the change in conformation of the EF-hand region activates the enzyme. If the EF-hand protein itself is not catalytic, the change in conformation causes the EF-hand protein to activate a target enzyme or structural protein.

The characteristics of 73 distinct EF-hand subfamilies are summarized in [Table 1](#). The functions of only 33 of the 73 are

known. Nine of these are enzymes and have been shown or inferred to be activated by the binding of calcium. Many, but certainly not all, of the remaining 64 such as calmodulin, function in information transduction pathways. However, others, such as calbindin D_{9k}, probably facilitate the diffusion of calcium through the cytosol; parvalbumin appears to function as a temporal buffer. Thirty-six, including the nine enzymes, of the 73 subfamilies are chimeric. In addition to their EF-hands, they contain other domains of different evolutionary origin and different conformation. Crystal structures are available for 23 of the subfamilies; nuclear magnetic resonance (NMR) structures are available for three additional subfamilies. Members of the penta-EF-hand subfamily (calpain, sorcin, peflin, grancalcin, and ALG-2) consist of two canonical EF-lobes (domains 1 and 2 and 3 and 4). These proteins form homo- or hetero-dimers by pairing their fifth EF-hands to form a canonical EF-lobe.

It is not unusual for a basic protein domain to find many uses, often spliced together with other domains; however, the EF-hand is one of the most widely distributed domains in eukaryotes, perhaps reflecting the range and subtlety of calcium signaling. The downstream regulation element antagonist modulator (DREAM) upon binding calcium dissociates from a DNA-binding regulatory element that otherwise functions as a gene silencer. This might provide a precedent for long-term potentiation.

Most classifications of proteins recognize the domain, for example, the EF-hand, as the fundamental unit of both evolution and structure. All homologous domains are assumed to have evolved from a single precursor domain in an ancestral organism. All domains in a single homolog family have similar

tertiary structures and, within the limits of statistical deviation, recognizably similar amino acid sequences. Exceptions may include short linker regions between domains and intrinsically disordered regions, both of which often contain tandem repeats of oligo-peptides or of single residues. Any given domain belongs to one domain family; by this definition, a domain cannot belong to two families. Many proteins consist of multiple domains; some are chimeric with domains from different families spliced together, reflecting gene fusion. Each domain in a multidomain protein has its own evolutionary history.

If two homologous domains within two proteins or within a single, multidomain protein were generated by gene duplication (followed by gene fusion in the multidomain protein), they are paralogs. If two proteins in two organisms were generated by speciation, they are orthologs. Two homologous proteins within a single species are, by definition, paralogs. Two proteins, one each from two different species, may be either paralogs or orthologs; the burden of proof lies with the advocate of orthology. A dendrogram relating orthologs should reflect the phylogeny of the host species, and, within statistical error, be identical to other dendrograms based on families of other orthologs from those same species.

A similar analysis can be applied to groups of proteins composed of several homologous domains, for example, the four EF-hands of calmodulin, troponin C, essential and regulatory light chains (CTER) from several species. All domains 1 cluster together, near the cluster of domains 3; all domains 2 cluster together, near the cluster of domains 4. This implies that all CTERs (and other proteins included in this group) evolved from a single, four EF-hand precursor by gene duplication and fusion with subsequent speciation. All of the subfamilies within

CTER are congruent. Further, this four-domain precursor evolved by gene duplication and fusion from a two-domain ODD, EVEN precursor. All EF-hands, with exceptions to be noted, occur as ODD, EVEN EF-lobes. Probably all EF-lobes evolved from a single EF-lobe, itself the result of the duplication of a single ur-EF-hand in an ancestor to all eukaryotes.

The characteristics of groups of subfamilies of EF-hands are summarized in [Table 1](#). Four groups of subfamilies – CTER (with 10 subfamilies), CPR (7), penta (5), and S100 (4) – show significant congruence, the basis for their classifications. The remaining five groups – eight and 12 EF-hand domains (2 subfamilies), six (6), four (19), two (17), and bacteria and virus (3) – reflect the number of domains or a noneukaryote host. The evolutionary relationships of the subfamilies within these groups are problematic. Parvalbumin is listed with the four EF-hand group because it probably evolved from a four-domain precursor, with the first (ODD) domain having been deleted. The host organism(s) are indicated as animal, plant, fungi, and/or protist (single cell). Also indicated are whether a function is known (+/-), whether a crystal or NMR structure is available (X,N/-), and whether the protein is chimeric (C/-) or consists solely of EF-hands.

For several of these 73 subfamilies, with few examples and limited functional information, the decision whether ‘to lump or to split’ is somewhat arbitrary. Thirty-six of the 72 are chimeric. In a few cases, this assignment depends on whether the non-EF-hand regions are considered to be canonical domains or tandem repeat linkers or intrinsically disordered regions.

Calmodulin

Calmodulin is probably present in all cells of all eukaryotes. It consists of four EF-hands and its amino acid sequence is highly conserved. The second α -helix of domain 2 (F2), an eight-residue linker, and the first α -helix of domain 3 (E3) forms a single continuous α -helix ~28 residues long, thereby giving calmodulin a dumbbell shape as seen both in crystals and in solution. Upon binding calcium, the relative orientations in both EF-lobes change, thereby exposing hydrophobic regions and permitting the interaction of calmodulin with over 40 different target enzymes and structural proteins. The structures of calmodulin complexed with α -helical regions of several targets, such as myosin light chain kinase (MLCK),

reveal what appears to be a general pattern for the interactions of four-domain EF-hand proteins, such as calmodulin, troponin C, and the essential and regulatory light chains of myosin, with their respective targets. MLCK is self-inhibited by its own peptide, 796–813; limited proteolysis removes this peptide. The 1–795 MLCK is then constitutively active. *In vivo*, calmodulin binds calcium, undergoes a change in conformation, binds α -helix, 796–813, of MLCK, and thereby removes the self-inhibition of MLCK. Calmodulin assumes near spherical shapes when complexed with its various targets, as opposed to the elongated dumbbell shape of uncomplexed calmodulin. The eight-residue linker is flexible, permitting calmodulin to assume a broad range of conformations. Several of these conformations match the many targets of calmodulin.

Glossary

G protein Protein associated to specific hormone receptor of the plasma membrane and responsible for the conversion of extracellular signals in intracellular messages.

Inositol (1,4,5)-trisphosphate (InsP₃) Diffusible cytosolic messenger which induces the release of Ca²⁺ from intracellular stores (the endo/sarcoplasmic reticulum) by opening InsP₃-sensitive Ca²⁺ channels.

Membrane potential Electrical gradient across the plasma membrane (and other membranes as well).

Neurotransmitters Chemical messengers by which neurons communicate with each other.

Nicotinamide adenine dinucleotide (NAD(P)H) Acceptor of the reducing equivalent produced in the oxidation of most metabolites. It is a small organic molecule, which participates as a coenzyme in enzymatic reactions.

General Considerations

It has been known since the 1950s that the periodic opening of plasma membrane Ca²⁺ channels, such as induced, for example, by the rhythmic changes of the plasma membrane potential of the heart or by burst of action potential in neurons, can produce fluctuations in cytosolic [Ca²⁺]. The idea that [Ca²⁺]_c oscillations may also occur in nonexcitable cells has emerged much later, thanks to seminal observations by Cobbold and co-workers in mid-1980s on the fertilization of oocytes and on hormone-stimulated hepatocytes. Surprisingly, these oscillations were not dependent on the periodic opening and closing of plasma membrane Ca²⁺ channels, but rather on cycles of Ca²⁺ release and uptake from the intracellular compartment sensitive to the second messengers inositol (1,4,5)-trisphosphate (InsP₃), which is the endoplasmic reticulum (ER). Later, Ca²⁺ oscillations were observed in other animals as well as plant cells, even if many of these cells do not have an obvious oscillatory biological function.

A question that immediately arises is the reason for the transmission of the Ca²⁺ signal by oscillations rather than by a stationary change in Ca²⁺ concentration. It is generally assumed that the oscillatory behavior has physiological advantages. This is so because the elevation of Ca²⁺ concentration over a long period is known to be lethal to the cell: the oscillatory behavior would prevent this negative effect, while still permitting optimal activation of Ca²⁺ sensing enzymes. The oscillatory regime would also prevent long-lasting receptor desensitization, thus increasing the sensitivity of sensing enzymes to Ca²⁺, that is, [Ca²⁺] would be permitted to periodically exceed the threshold for enzyme activation, even its level would remain below the threshold. Another advantage is the wide range of temporal and spatial aspects that oscillations can assume, allowing different signals to be transmitted within cells and from cell to cell.

Usually, Ca²⁺ oscillations are characterized by rather constant amplitude and by a variable frequency, which ranges from 5 to 60 seconds depending on the cell type, and on the nature and the strength of the stimulus (Figure 1). These characteristics have led to the concept of frequency-modulated Ca²⁺ signaling, which reflects the ability of cells to interpret changes in the frequency of the oscillations.

Mechanism of [Ca²⁺]_c Oscillations

Although the mechanism of Ca²⁺ oscillation has received much experimental and theoretical attention, it is still largely debated. A first distinction considers the origin of the Ca²⁺ spikes, for which two major mechanisms exist: one is linked to the periodic opening of plasma membrane channels and the other to cycles of Ca²⁺ release and uptake from intracellular stores (Figure 2). However, this distinction is incomplete since very often the contributions of intracellular Ca²⁺ release and of extracellular Ca²⁺ influx cannot be clearly separated. An obvious example is that of cardiac myocytes, where the periodic contraction of the cells is directly promoted by the release of Ca²⁺ from the sarcoplasmic reticulum (SR), which is triggered by localized influx of Ca²⁺ through plasma membrane voltage-operated Ca²⁺ channels (VOCs), a process known as Ca²⁺-induced Ca²⁺ release (CIRC).

In excitable cells such as neurons, heart, and neuroendocrine cells, the transient [Ca²⁺] elevation is due to Ca²⁺ entry through VOCs or receptor-operated Ca²⁺ channels (ROCs) activated in response to neurotransmitters. In these cells, the oscillatory behavior is secondary to the oscillatory nature of the trigger itself. For example, cortical and cerebellar neurons in primary cultures exhibit spontaneous oscillations, which occur in synchrony with adjacent neurons and are dependent on synaptic activity, that is, changes of membrane potential.

In nonexcitable cells the predominant mechanism of [Ca²⁺]_c elevation is through the activation of plasma membrane receptors coupled to G proteins and the phosphoinositide pathway. Activation of membrane phospholipase C (PLC) generates the second-messenger InsP₃ from phosphatidylinositol 4,5-bisphosphate, mobilizing Ca²⁺ from stores, associated with the ER or SR. The pattern of the Ca²⁺ signals is often complex but InsP₃-linked agonists frequently give rise to repetitive [Ca²⁺]_c transients.

Other molecules (i.e., cyclic adenosine diphosphate (ADP)-ribose (cADPR) and nicotinic acid adenine dinucleotide phosphate (NAADP)) have recently also been shown to mobilize Ca²⁺ from internal stores generating Ca²⁺ oscillations. Studies using Ca²⁺ indicator dyes targeted to the lumen of intracellular stores of intact cells have shown that agonist-induced cytosolic Ca²⁺ oscillations are accompanied by inverse oscillations of stored Ca²⁺.

Figure 1 Examples of different oscillatory pathways: (a) parotid gland; (b) hepatocyte; and (c) endothelial cell. The pattern of oscillations may vary with respect to amplitude and period. The red arrow indicates agonist stimulation.

Recent works suggest at least two possible mechanisms for the generation of oscillatory Ca^{2+} signals: either an oscillatory production of InsP_3 or an oscillatory inactivation of InsP_3 receptors. Both mechanisms appear to operate in different cell types, the common denominator being the positive and negative feedback by Ca^{2+} on the release system; for example, in hormone-stimulated hepatocytes, oscillations are driven by the cycling of the InsP_3 channels between a fully open and a largely closed state, rather than by oscillations in InsP_3 . Similarly, in pancreatic acinar cells, the pulsatile calcium release does not depend on fluctuations in InsP_3 concentration, but in kidney epithelial cells spatiotemporal changes in the concentration of InsP_3 appear to be synchronous with Ca^{2+} oscillations, and intracellular InsP_3 waves accompany Ca^{2+} waves.

The fluctuations in InsP_3 may be controlled by Ca^{2+} itself through the regulation of PLC activity or through regulatory proteins which act directly on G proteins, thus affecting the downstream InsP_3 production. Alternatively, the activity of the InsP_3 -sensitive Ca^{2+} channels may be controlled by Ca^{2+} itself at both the cytosolic and the luminal side, and, possibly, by kinase-mediated phosphorylation/dephosphorylation cycles. Thus, low concentrations of cytosolic Ca^{2+} increase the open

probability of the channels, whereas higher concentrations favor their closure, generating the oscillatory Ca^{2+} -signaling pattern.

Another intriguing aspect that has recently emerged is that it is clear that influx of Ca^{2+} across the plasma membrane also plays a critical role in maintaining Ca^{2+} oscillations and in delivering their signal to the correct cellular locus. As ER Ca^{2+} levels drop (as a consequence of physiological receptor activation), Ca^{2+} enters through highly specific store-operated channels (SOCs) in the plasma membrane that are controlled by stromal-interacting molecule (STIM) proteins, sensors of ER luminal Ca^{2+} levels. STIM1 protein is shown to translocate cyclically in and out of ER-plasma membrane junctions during each Ca^{2+} oscillatory spike, thus activating Orai1 channels and Ca^{2+} entry. The elimination of STIM1 or Orai1 channels suppresses the oscillations.

Role and Functional Significance of $[\text{Ca}^{2+}]_c$ Oscillations

Ca^{2+} oscillations have been implicated in the control of different cell processes, including oocyte activation and fertilization, growth-cone migration, growth-cone tuning, axonal growth of cortical neurons, neuronal-cell migration, development of neurotransmitter phenotypes, formation of nodules in plant root hairs, development of muscle, release of cytokines from renal epithelial cells, and disassembly of adhesive structures during cell migration (Figure 3).

Numerous experimental protocols modulate the amplitude and the frequency of Ca^{2+} spikes in living cells. In general, cells choose the shape of Ca^{2+} signals according to the type of process that must be activated: single Ca^{2+} transients are used to activate processes such as muscle contraction, and repetitive signals are used when information must be relayed over long time periods, as in fertilization and in the triggering of the developmental program. Furthermore, oscillations can be directed to discrete subcellular domains to generate large local $[\text{Ca}^{2+}]_c$ increases required to couple $[\text{Ca}^{2+}]_c$ to secretion and to mitochondrial metabolism. They can also propagate through entire cells, or even through coupled cells to coordinate the activities in intact tissues and organs.

The most obvious mechanism for the regulating of specific functions would seem to be modulation of the amplitude of Ca^{2+} signals. However, the efficiency of the activating stimulus is frequently related to the frequency rather than to the amplitude of the $[\text{Ca}^{2+}]_c$ oscillations.

A particularly illustrative example of decoding of the Ca^{2+} signal through the frequency of the oscillations is the Ca^{2+} -regulated gene expression.

Dolmetsch and colleagues have recently reported that Ca^{2+} oscillations in T-lymphocytes reduce the effective Ca^{2+} -threshold for activating some transcription factors, more effectively than the sustained Ca^{2+} increase. The efficacy is encoded by the oscillation frequency: rapid oscillations stimulate three transcription factors (nuclear factor of activated T-cells (NF-AT), Oct/OAP, and nuclear factor kappaB (NF- κ B)), while lower frequency oscillations only activate NF- κ B. Thus, Ca^{2+} -modulated gene transcription is a frequency-sensitive process. Another elegant example of the correlation between the frequency of the $[\text{Ca}^{2+}]_c$ spikes and cellular function is the

Figure 2 Signaling pathways that participate in the generation of Ca^{2+} oscillations. Three models are proposed. In excitable cells, Ca^{2+} oscillations are evoked by rhythmic oscillatory changes in membrane potential. In nonexcitable cells they are induced either by the oscillatory production of InsP_3 or following the oscillatory inactivation of InsP_3 receptors (ON/OFF). ER/SR, endoplasmic/sarcoplasmic reticulum; PLC, phospholipase C; SERCA, sarco/endoplasmic reticulum calcium ATPase; InsP_3 , inositol 1,4,5-trisphosphate; cADPR, cyclic ADP-ribose; NAADP, nicotinic acid adenine dinucleotide phosphate.

Figure 3 Scheme of the main cellular events modulated by the oscillatory behavior of Ca^{2+} signal.

translation of repetitive cytosolic Ca^{2+} spiking through mitochondrial Ca^{2+} oscillations in primary cultures of rat hepatocytes in the final and sustained elevation of nicotinamide adenine dinucleotide (NAD(P)H) production. This coupling allows the coordination of mitochondrial adenosine triphosphate (ATP) production, linked to the sustained activation of mitochondrial Ca^{2+} -sensitive dehydrogenases, with the level of energy demand, at the same time avoiding the deleterious effects of the prolonged $[\text{Ca}^{2+}]$ increases.

In polarized cells, such as those of pancreatic acini, the receptor-evoked Ca^{2+} signal initiates at the apical pole,

generating agonist-specific Ca^{2+} oscillation patterns. Acetylcholine stimulation evokes repetitive local spikes, which remain confined to the secretory apical pole. Cholecystokinin instead induces local Ca^{2+} spikes that end in longer-lasting Ca^{2+} transients that spread to the whole cell.

Last but not least, in considering the functional significance of Ca^{2+} oscillations it is necessary to empathize their role in the central nervous system. In neurons, the sequential openings of plasma membrane Ca^{2+} channels lead to rhythmic Ca^{2+} spikes that, in turn, are linked to synaptic communication within and among neuronal circuitries, that is, by inducing neurotransmitter

release. A peculiar role has been recently attributed to the spontaneous and synchronous Ca^{2+} oscillations that occur independently from synaptic activity in developing neurons, such as those in rat visual cortex. It was suggested that these oscillations could propagate through different cells and determine a common developmental pattern of cells from the same domain.

A sophisticated example of the role of Ca^{2+} oscillation in the coordination of the activity of neuronal circuits has been described in glial astrocytes, a cell type of the central nervous system, which plays a number of important functions. Very recently, it has been proposed that they work as detectors of synaptic activity: by changing the frequency of Ca^{2+} oscillations evoked by the synaptic release of glutamate these astrocytes acquire the ability to discriminate between different levels and patterns of synaptic activity.

How Are $[\text{Ca}^{2+}]_c$ Oscillations Decoded?

Although the frequency of Ca^{2+} oscillations seems critical for the induction of selective cellular functions, the mechanisms by which the cell decodes the oscillatory signal remain unclear.

In 1998 De Koninck and Schulman showed that the oscillation frequency modulates the activity of Ca^{2+} -calmodulin kinase II (CaMKII) *in vitro*. This enzyme is tuned to respond optimally to Ca^{2+} oscillations with high frequency. The multimeric structure of the enzyme, coupled to its autophosphorylation properties, has led to the suggestion that it can act as a frequency decoder of $[\text{Ca}^{2+}]_c$ oscillations. The enzyme is now considered of special importance to the nervous system, where it regulates the process of memory formation and storage.

The advent of the green fluorescent protein (GFP) technology has shown that protein kinase C (PKC), one of the most important enzymes in cell signaling, undergoes an oscillatory plasma membrane association in phase with receptor-mediated oscillations in $[\text{Ca}^{2+}]_c$. Each $[\text{Ca}^{2+}]_c$ oscillation induces the

transient membrane association of PKC leading to a transient burst of PKC substrate phosphorylation. It was suggested that the detachment of PKC from the membrane, which occurs as Ca^{2+} returns to the basal level between oscillations, results in a pause of PKC activity, allowing substrate dephosphorylation. In this respect, the Ca^{2+} -mediated regulation of PKC differs from that of CaMKII, since the latter does not fully deactivate between spikes as the frequency of $[\text{Ca}^{2+}]_c$ oscillations increases.

The matter of decoding Ca^{2+} oscillations however is even further complex since emerging evidence highlights the possibility that Ca^{2+} oscillations that are identical in amplitude and frequency should differentially activate downstream targets depending on spatial location of the underlying Ca^{2+} channels: only oscillations with accompanying Ca^{2+} entry through SOCs triggered gene expression, and Ca^{2+} entry is needed to sustain Ca^{2+} oscillations.

Glossary

Autosomal dominant hypoparathyroidism

(ADH) A generally benign form of hypocalcemia caused by gain-of-function mutations in the CaSR.

Calcilytic An inhibitor of the CaSR.

Calcimimetic An allosteric activator of the CaSR.

Calcium-sensing receptor (CaSR) A G-protein-coupled receptor maintaining the near constancy of extracellular calcium.

Familial hypocalciuric hypercalcemia (FHH) A benign form of hypercalcemia caused by loss-of-function mutations in the CaSR.

Neonatal severe primary hyperparathyroidism

(NSHPT) An autosomal recessive disease usually caused by loss-of-function mutations of both alleles of the CaSR.

Background

The body maintains the level of extracellular free (i.e., unbound) calcium ($\text{Ca}^{2+}_{\text{o}}$) within a narrow range (1.1–1.3 mM) because both high and low levels of $\text{Ca}^{2+}_{\text{o}}$ are dangerous and can be life threatening. Very small changes in $\text{Ca}^{2+}_{\text{o}}$, on the order of a few percent, lead to immediate physiological responses that restore the level of $\text{Ca}^{2+}_{\text{o}}$ to normal. These fast responses are essential because rapid changes in $\text{Ca}^{2+}_{\text{o}}$ are more dangerous than those that develop more slowly. The calcium-sensing receptor (CaSR), which was cloned more than a decade ago, plays a central role in this delicate homeostatic system. The CaSR acts like a thermostat, but instead of measuring changes in temperature it measures alterations in the level of $\text{Ca}^{2+}_{\text{o}}$, thereby functioning as a calcistat. This means that the CaSR tells the chief cells of the parathyroid glands the exact level of $\text{Ca}^{2+}_{\text{o}}$. The CaSR is a seven-transmembrane-domain (TMD) receptor that is coupled to G proteins – a so-called G-protein-coupled receptor (GPCR). The importance of the CaSR is illustrated by the diseases caused by naturally occurring mutations in it that lead to either loss of function or gain of function. Heterozygous (one allele) loss-of-function mutations give rise to a generally benign condition called ‘familial hypocalciuric hypercalcemia (FHH)’, also called ‘familial benign hypocalciuric hypercalcemia (FBHH)’, in which most affected individuals have asymptomatic hypercalcemia. The homozygous variant of inactivating CaSR mutations, in contrast, is a much more severe, potentially fatal disease if left untreated; it is called ‘neonatal severe primary hyperparathyroidism (NSHPT)’. The mouse model of FHH (e.g., heterozygous knockout of the CaSR gene) has a phenotype comparable to that of the human condition, suggesting that the number of receptors on the cell surface is the determining factor for the clinical expression of the disease. Gain-of-function mutations give rise to autosomal-dominant hypoparathyroidism (ADH). Most individuals with this condition have asymptomatic hypocalcemia. Although the principal role for the CaSR is in calcium homeostasis, other functions of

the receptor have been elucidated in the wide variety of cell types expressing it. The CaSR can regulate the cell cycle, ion channels, peptide secretion, and diverse other functions. This article provides a broad overview of the CaSR’s biochemical features, a discussion of its functions in normal and pathophysiological states, and a discussion of new drugs that have been developed that target the CaSR.

Biochemical Features of the CaSR

The CaSR is a seven-TMD GPCR whose gene is located on chromosome 3q13. Other receptors in the superfamily of GPCRs that are related structurally to the CaSR include the gamma aminobutyric acid type B (GABA_{B}) and metabotropic glutamate receptors (mGluRs), which recognize GABA and glutamate, respectively, as their ligands, as well as pheromone, taste, and odorant (in fish) receptors.

Structure

The human CaSR has a very large N-terminal extracellular domain (ECD) of 612 amino acids and has a bilobed Venus flytrap structure (VFT) (Figure 1). The ECD contains key binding sites for calcium, although there is at least one additional site(s) in the receptor’s central core of 250 amino acids, including the TMDs and/or associated extracellular loops (ECLs). Binding of Ca^{2+} (the CaSR’s principal physiological ligand) to the ECD is thought to close the VFT, in association with additional conformational changes in the ECD and/or TMDs that activate signal transduction. The binding of $\text{Ca}^{2+}_{\text{o}}$ is very weak compared to the affinities of many other receptors for their ligands. These weak forces between the ECD and $\text{Ca}^{2+}_{\text{o}}$ are crucial for the receptor to act as a calcistat. The TMDs also serve as the target for newly developed drugs that act as allosteric activators (calcimimetics) or inhibitors (calcilytics) of the CaSR (discussed later). The intracellular carboxy (C)-terminus of the receptor consists of 216 amino acids and has important roles, along with the CaSR’s intracellular loops

Figure 1 Representation of the predicted structure of the bilobed dimeric, 612 amino acid ECDs of the human extracellular Ca^{2+} -sensing receptor based on the known structure of the ECDs of several mGluRs. Also shown schematically in the ECDs are the positions of the putative Ca^{2+} -binding sites in the crevice between lobes 1 and 2. Cys 129 and Cys 131 indicate the locations of the disulfide bonds between the flexible loop 2 of each ECD. Shown in simplified form in the bottom half of the picture are the receptor's TMDs, extra (ECLs)- and intracellular loops (ICLs), and intracellular C-tail (C-tail). This research was originally published in Huang Y, Zhou Y, Yang W, et al. (2007) Identification and dissection of Ca^{2+} -binding sites in the extracellular domain of Ca^{2+} -sensing receptor. *Journal of Biological Chemistry* 282(26): 19000–19010. © The American Society for Biochemistry and Molecular Biology.

(ICLs), in the transduction of the Ca^{2+} signal to inside the cell (see below).

N-Glycosylation with carbohydrates is crucial for cell surface expression

The CaSR has several N-linked glycosylation sites that are important for its expression on the cell surface. Western blotting of the CaSR shows several bands between 120 and 200 kDa. A minor band at 120 kDa represents the nonglycosylated CaSR, whereas major bands at about 140 and 160 kDa correspond to the immature, high mannose and mature, fully N-glycosylated forms of the CaSR, respectively. If the degree of glycosylation of the receptor is reduced to a significant extent by site-directed mutagenesis of its N-linked glycosylation sites, less of the receptor reaches the cell surface, thereby indirectly reducing the activity of the receptor, although the intrinsic activity of the receptor is not thought to be directly linked to glycosylation.

CaSR functions as a dimer on the cell surface

Additional immunoreactive bands observed on Western blot analysis of the CaSR at >200 kDa represent CaSR dimers or even larger species. The fully glycosylated, ~320-kDa dimer is the major form of CaSR on the cell surface and is thought to be the active form of the receptor. Two monomers of the CaSR are linked covalently by two disulfide bonds involving cysteine residues 129 and 131 as well as by noncovalent, hydrophobic interactions. The disulfide bonds constrain the receptor in its inactive form; disrupting them by site-directed mutagenesis or naturally occurring mutations produces a receptor that responds to lower than normal levels of Ca^{2+} . Moreover, heterodimerization of a normal CaSR monomer with a monomer harboring an FHH mutation can interfere via a dominant negative mechanism with the function of the wild-type CaSR

monomer, documenting that there are functional interactions between the monomers of the dimeric CaSR. The CaSR can also heterodimerize with the GABA_B receptor, which modulates the function of both heterodimeric partners.

Amino acids in ICLs are pivotal for activation of intracellular signaling by the CaSR

Amino acids in ICLs 2 and 3 are key players in determining selective coupling of the CaSR to G proteins. For example, two amino acid residues within ICL 2 and eight residues in ICL 3 have been shown to be important for the G-protein-dependent activation of phospholipase C (PLC) – one of the major intracellular signaling pathways used by the CaSR.

The C-tail of the CaSR is important for its function

The amino acid sequence of the proximal portion of the C-tail of the CaSR is highly conserved among species, suggesting its functional importance. In addition, naturally occurring mutations in the C-tail have been shown to cause the diseases mentioned earlier (e.g., FHH and ADH). Furthermore, certain truncation and deletion mutations of the receptor's C-tail upregulate the expression of the receptor on the cell surface, thereby causing gain of function. Other truncations cause loss of function, demonstrating that there are discrete elements within the C-tail that modulate both the cell surface expression and the function of the receptor. The CaSR has several binding partners that interact with the CaSR's C-tail, thereby affecting the function of one or both of the two partners. These include filamin-A, a large actin-binding protein that can serve as a scaffold protein (e.g., for mitogen-activated protein kinases (MAPK)), dorfin, which likely regulates proteasomal degradation of the receptor, receptor activity modifying proteins (RAMPs), and potassium channels.

Functionally important mutations in the CaSR as experiments in nature

Approximately 200 naturally occurring mutations have so far been described that cause either a loss of function of the CaSR in FHH and NSHPT or a gain of function in ADH. Deletion, nonsense, insertion, missense, truncations, and splice-site mutations have been described throughout the whole CaSR gene. They have not only proven the physiological importance of the CaSR in Ca^{2+} homeostasis, but also provided an important source of information about the structure–function relationships of the receptor, as noted previously. There are several polymorphisms present within the CaSR's C-tail and elsewhere. Available evidence suggests that they may contribute to the variation in the range of serum calcium concentrations among normal individuals and modify the severity of diseases of calcium homeostasis, such as primary and secondary hyperparathyroidism. Inactivating or activating antibodies to the CaSR causes conditions phenotypically similar to FHH and ADH, respectively.

Agonists of the CaSR

As previously mentioned, the CaSR can detect very small changes in Ca^{2+}_o , on the order of a few percent. As noted above, calcium interacts with the ECD of the CaSR. This has been established elegantly through the creation of a chimeric receptor containing the CaSR's ECD and the TMDs and C-tail of an mGluR. The chimeric receptor responds to Ca^{2+}_o but not to glutamate. A key Ca^{2+} -binding site likely resides within the crevice between the two lobes of each monomeric VFT. The CaSR's Hill coefficient is typically 3–4, implying the presence of additional binding sites for Ca^{2+}_o , yet to be definitively identified; the steepness of the physiological response of the parathyroid glands to Ca^{2+} is even more extreme. As a result, suppression of parathyroid hormone (PTH) release *in vitro*, and *in vitro* occurs over a very narrow range of Ca^{2+} , between about 0.75–1.0 mM and 1.5–2 mM. Unlike many receptors, the CaSR is relatively resistant to desensitization; this optimizes its capacity, especially in the parathyroid gland, for continuous surveillance of extracellular Ca^{2+} levels. Although Ca^{2+}_o is the major ligand for the CaSR, a variety of other agonists have been identified. Mg^{2+} (another biologically important divalent cation whose extracellular level is maintained within a narrow range similar to, albeit slightly lower than, that of Ca^{2+}) has been shown, like Ca^{2+}_o , to inhibit PTH secretion. Although this effect seems to occur at supraphysiological levels, magnesium's action on the CaSR in the kidney, where the local concentration of Mg^{2+} can be higher, may regulate its renal reabsorption and contribute to Mg^{2+}_o homeostasis.

Other well-established agonists acting on the CaSR's ECD are gadolinium, neomycin, and spermine; all of which exhibit positive cooperativity with regard to their interactions with calcium in activating the receptor. These three agonists, as well as Mg^{2+}_o , are defined as type 1 agonists, which bind to the ECD and activate the CaSR regardless of whether Ca^{2+}_o is present. Type 2 agonists, by contrast, are allosteric activators that require calcium to exert their effects. Certain L-amino acids, particularly aromatic amino acids, have been shown to be type 2 agonists, binding to a site within the CaSR's ECD

close to that of Ca^{2+} . It is possible that they function in this manner in the gut, where the CaSR is widely distributed, enabling the CaSR to act, in effect, as a nutrient receptor. The CaSR also senses ionic strength, as illustrated by the fact that exposing dispersed bovine parathyroid cells to a 40-mM increment in NaCl shifts the EC_{50} for high Ca^{2+}_o -evoked inhibition of PTH release by at least 0.5 mM. Ionic strength may exert physiologically relevant actions on the CaSR in select regions of the gastrointestinal (GI) tract and kidney, where the levels of ionic strength can vary greatly.

Intracellular Signaling Pathways Utilized by the CaSR

CaSR agonists activate phospholipases C, A_2 , and D in parathyroid as well as in CaSR-transfected but not in nontransfected human embryonic kidney (HEK293) cells. The high Ca^{2+}_o -evoked, transient rise in the cytosolic calcium concentration (Ca^{2+}_i) in bovine parathyroid and CaSR-transfected HEK293 cells is mediated by activation of PLC and the resultant inositol triphosphate (IP_3)-mediated release of Ca^{2+} from intracellular stores. In parathyroid and CaSR-transfected HEK293 cells, the activation of PLC is insensitive to pertussis toxin and involves $\text{G}_{\alpha_{q/11}}$. The CaSR also stimulates the p42/44 and p38MAPKs as well as the c-Jun-N-terminal kinase (JNK) by pathways that involve protein kinase C and/or cytoplasmic tyrosine kinases (e.g., c-Src) and inhibit adenylate cyclase via G_{α_i} in parathyroid and some kidney cells. In other cells, the CaSR inhibits the accumulation of cyclic adenosine monophosphate (cAMP) by increasing Ca^{2+}_i , which then inhibits the activity of a Ca^{2+} -inhibitable isoform of adenylate cyclase. Additional CaSR-linked signaling pathways include stimulation of ceramide generation and activation of Rho kinase, phosphatidylinositol 3-kinase (Akt), and phosphatidylinositol 4-kinase.

Feedback regulation of the CaSR by protein kinase C

The CaSR has two protein kinase A (PKA) and five protein kinase C (PKC) phosphorylation sites within its intracellular domains. Phosphorylation of these PKC sites, especially the one located at threonine 888, inhibits the receptor's coupling to PLC, one of the CaSR's principal intracellular signaling pathways. This serves as a negative feedback loop because PKC is activated downstream of PLC. Phosphorylation of the PKA sites has only minor impact on the receptor's function.

The Importance of the CaSR in Calcium Homeostasis

The level of calcium in the blood is regulated by three calcitropic hormones: PTH, calcitonin (CT), and $1,25(\text{OH})_2$ vitamin D_3 . There is an inverse sigmoidal relationship between PTH, a key calcium-elevating hormone, and Ca^{2+}_o (Figure 2), whereas there is a positive relationship between Ca^{2+}_o and CT, the calcium-lowering hormone, both of which are mediated by the CaSR. These features confer on the CaSR the role of the gatekeeper to normal calcium homeostasis. The additional Ca^{2+}_o -elevating hormone, $1,25(\text{OH})_2$ vitamin D_3 , like PTH, displays an inverse relationship with Ca^{2+}_o , which is likely also CaSR mediated. In addition to the effects of the

Figure 2 Sigmoidal relationship between the B-Ca²⁺ and serum PTH (S-PTH) levels in normal individuals (eucalcemia), in autosomal dominant hypoparathyroidism (ADH) (hypocalcemia), and in familial hypocalciuric hypercalcemia (FHH). The arrows represent the effects of calcimimetics (shifting the set point to the left) and calcilytics (shifting the set point to the right). Set point is defined as the level of calcium that produces one-half of the maximal inhibition of PTH secretion. Reproduced from Tfelt-Hansen J, Schwarz P, Brown EM, and Chattopadhyaya N (2003) *Frontiers in Bioscience* 8: S377–S390.

CaSR on calciotropic hormone production and secretion, the receptor also directly modulates the function of target tissues for PTH, especially in the kidney and perhaps in the bone and intestine. In this way, Ca²⁺_o functions as a first messenger, serving as the body's major Ca²⁺_o-lowering hormone (described later).

Role of the CaSR in the Defense against Hypercalcemia

The responses of the CaSR to hypercalcemia provide an instructive example of its role in calcium homeostasis.

Parathyroid

An increase in Ca²⁺_o is sensed by the chief cells in the parathyroid gland, which within seconds lowers the rate of PTH secretion. Additional CaSR-mediated effects of hypercalcemia on parathyroid function are inhibition of PTH gene expression, suppression of parathyroid proliferation, and upregulation of the vitamin D receptor (VDR), which mediates the inhibitory actions on 1,25(OH)₂D₃ on parathyroid function. The phosphaturic hormone, fibroblast growth factor-23 (FGF-23), is another, recently described, negative regulator of parathyroid function, although its importance in Ca²⁺_o homeostasis is not fully elucidated. The impact of the hypercalcemia-evoked reduction in PTH secretion and the resultant direct and indirect actions of Ca²⁺_o on cellular function occur in several target tissues.

Bone

The high Ca²⁺_o-elicited lowering of PTH decreases the rate of release of calcium ions from bone – an action mediated through its action on the PTH receptor (PTHr) on the osteoblast. The production of 1,25(OH)₂D₃ is likewise inhibited by hypercalcemia – and this fall in 1,25(OH)₂D₃ also reduces bone resorption. High Ca²⁺_o, by itself, also exerts negative

effects on osteoclast formation and function and increases osteoblast activity, thereby reducing the net release of calcium from bone. Taken together, the effects of PTH, 1,25(OH)₂D₃, and Ca²⁺_o on bone all promote lowering of the level of blood calcium.

Kidney and intestine

The high Ca²⁺_o-elicited decrease in the circulating level of PTH also promotes rapid excretion of calcium by the kidney. This action is thought to take place through a reduction in PTH-stimulated calcium reabsorption in the thick ascending limb of the loop of Henle as well as in the distal convoluted tubule. However, high Ca²⁺_o also directly inhibits renal tubular calcium reabsorption by virtue of the presence of the CaSR on the basolateral surface of the epithelial cells of the thick ascending limb, where the receptor antagonizes the stimulatory action of PTH on calcium reabsorption. Both the high Ca²⁺_o-elicited decrease in PTH and the direct inhibitory action of high Ca²⁺_o on the 1-hydroxylation of 25-hydroxyvitamin D₃ also inhibit the production of 1,25(OH)₂D₃, thereby reducing the absorption of Ca²⁺_o by the intestine. All these effects of hypercalcemia on the kidney, and indirectly on the intestine, reduce the level of Ca²⁺_o toward normal. When combined with the effects of a reduction in PTH and an increase in Ca²⁺_o on bone, the Ca²⁺_o homeostatic system provides an elegant mechanism for maintaining near constancy of Ca²⁺_o.

Nonhomeostatic Functions of the CaSR

Although the physiological roles of the CaSR in cells that do not participate in mineral ion homeostasis still remain to be fully defined, studies of the CaSR's functions in these diverse cell types have widened the range of functions that the CaSR is known to regulate. These CaSR-modulated processes include (1) regulating the secretion of peptides, for example,

adrenocorticotrophic hormone (ACTH), gastrin, insulin, growth hormone, rennin, and parathyroid hormone-related protein (PTHrP); (2) modulating ion channel/transporter activity, for example, aquaporin-2 water channels, nonselective cation channels, voltage-dependent Ca^{2+} channels, and calcium-activated potassium (K^+) and other K^+ channels; (3) controlling gene expression, for example, increasing expression of the vitamin D receptor and the CaSR itself; (4) stimulating the proliferation of ovarian surface epithelial cells and fibroblasts, and inhibiting that of parathyroid cells, keratinocytes, and colonic cells; (5) promoting the differentiation of keratinocytes, goblet cells, and mammary epithelial cells; (6) regulating the apoptosis of fibroblasts, HEK-293 cells stably transfected with the CaSR, and prostate cancer cells; (7) enhancing the chemotaxis of preosteoblastic cells and macrophages; and (8) promoting cellular adhesion (i.e., of hematopoietic stem cells to their bone marrow niche). Thus, Ca^{2+}_o may serve as an extracellular messenger regulating diverse cellular functions, not only in cells directly involved in Ca^{2+}_o homeostasis but also in the variety of additional cell types expressing the CaSR that play no apparent role in this process. In addition, increasing evidence implicates the CaSR in diseases of various non-homeostatic tissues, such as in suppressing the development of colon and breast cancer, inhibiting vascular calcification and atherosclerosis in CKD, and modulating the risk of pancreatitis.

Pharmaceutical Aspects

The CaSR has become a drug target as a consequence of its central role in calcium homeostasis and the evidence given earlier that it contributes to hyper- and hypocalcemic states. There are two classes of drugs acting on the CaSR. One group activates the receptor – these are allosteric activators and are called ‘calcimimetics’. The other group inhibits the effect of Ca^{2+}_o on the CaSR – these agents are called ‘calcilytics’.

Calcimimetics

Calcimimetics are type 2 activators that bind to the receptor’s TMDs and potentiate the action of Ca^{2+}_o on the CaSR. NPS R-568 and cinacalcet are two such agents; they shift the curve for Ca^{2+}_o -regulated changes in Ca^{2+}_i and PTH release to the left without affecting the maximal or minimal responses (Figure 2). Clinical trials have shown that cinacalcet can effectively lower serum PTH concentration in patients with stage 5 chronic kidney disease (CKD) (i.e., those receiving dialysis

treatment), and it has received regulatory approval for use in this setting. Cinacalcet is also approved for the treatment of hypercalcemia in patients with parathyroid carcinoma. Cinacalcet normalizes serum calcium concentration in the majority of patients with mild primary hyperparathyroidism. It has been approved for use in this setting in Europe but not in the US. The drug has been utilized in various other clinical settings but it has not been approved for any of these.

Calcilytics

This group of agents has the opposite effect, inhibiting the receptor and thereby stimulating PTH secretion (Figure 2). This class of drugs could potentially be useful in the treatment of osteoporosis by providing brief pulses of endogenous PTH secretion. The resultant transient increase in PTH mimics the elevation in PTH caused by once daily administration of exogenous PTH by subcutaneous injection. The latter is known to exert anabolic actions on bone and is approved by the US FDA for use in the treatment of osteoporosis. Clinical trials are underway investigating the safety and efficacy of various short-acting calcilytics as a treatment for osteoporosis.

Glossary

Acrosome reaction A Ca^{2+} -mediated process occurring in the sperm upon its interaction with the egg envelopes. In echinoderms, following sperm receptor activation, the globular actin in the acrosome vesicle polymerizes to form filaments that extend outside the sperm head to reach the egg surface. In the reaction, lytic enzymes are liberated by the sperm to facilitate its penetration through the egg envelopes.

Cortical reaction A massive exocytosis of the cortical granules (acidic secretory vesicles) located beneath the egg plasma membrane. Shortly after egg activation by the sperm, these granules fuse with the plasma membrane and discharge their contents into the perivitelline space

beneath the vitelline coat. The latter becomes altered, permitting the formation and elevation of the fertilization envelope.

Ectoenzyme Enzyme located in the plasma membrane with the active site facing the extracellular medium.

Inositol 1,4,5-trisphosphate (InsP_3), cyclic ADP-ribose (cADPr), nicotinic acid adenine dinucleotide phosphate (NAADP) Second messengers that liberate Ca^{2+} from intracellular organelles.

Intracellular calcium-releasing receptors Proteinaceous structures in the membranes of organelles that bind second messengers to activate a channel in the structure that lets through Ca^{2+} .

Ca^{2+} -Releasing Activity of Nicotinamide Adenine Dinucleotide and Nicotinamide Adenine Dinucleotide Phosphate

The development of a cell-free system using sea urchin egg homogenates and purified microsomes derived from the endoplasmic reticulum (ER) that possessed adenosine triphosphate (ATP)-dependent Ca^{2+} sequestration showed that sea urchin eggs possess systems for releasing Ca^{2+} from internal stores different from those activated by 1,4,5-inositol trisphosphate (InsP_3). Since it was already known that the concentrations of pyridine nucleotides dramatically changed after fertilization, a series of phosphorylated molecules were assayed to determine whether they could release Ca^{2+} . It was thus found that, in addition to InsP_3 , the oxidized form of nicotinamide adenine dinucleotide (NAD^+) and its phosphorylated form (NADP^+) were effective in releasing Ca^{2+} from the sea urchin homogenate system. While InsP_3 and NADP^+ released Ca^{2+} immediately upon addition, the release induced by NAD^+ showed a lag period of 1–2 min. These results suggested the enzymatic conversion of NAD^+ to a true Ca^{2+} -releasing metabolite. The metabolite was indeed purified, crystallized, and characterized as a cyclized adenosine diphosphate (ADP)-ribose (cADPr) which is synthesized from NAD^+ by the ADP-ribosyl cyclase (ARC), a soluble 29-kDa protein first purified from the sea snail *Aplysia californica*. ARC was prominently localized on granules and vesicles of immature oocytes in the *Aplysia* ovotestis: its crystallized structure showed extensive sequence similarity to human CD38, a type II cell surface transmembrane glycoprotein involved in the regulation of lymphocyte adhesion to endothelial cells, and to CD157 (BST-1), another related molecule with similar enzyme activities. Both CD38 and CD157 are ecto-enzymes, the catalytic domains of which are located outside the cell. They have both ARC and cADPr hydrolase activities, that is, they synthesize cADPr from NAD^+ and hydrolyze it to ADP-ribose.

The localization of the active site of CD38 at the ectocellular domain raised a number of questions on the mechanism of the CD38/cADPr system. The ectocellular synthesis of cADPr whose

only known function, that is, calcium mobilization, is necessarily intracellular was apparently paradoxical. Somehow, cADPr could gain access to the interior of the cells. Extracellular cADPr, either produced by CD38 or directly added to the medium, elicited an enhanced intracellular Ca^{2+} response in several cell types including fibroblasts. Thus, the possibility that CD38, in addition to generating cADPr, could actively transfer it across the plasma membrane into the cytosol is plausible.

The initial studies on the receptor function of CD38 showed that it not only mediated cell adhesion but also initiated transmembrane signaling in response to the interaction with its ligand CD31 or with agonistic CD38 antibodies, which resulted in tyrosine phosphorylation of intracellular proteins such as extracellular signal-regulated kinase (ERK) and the c-cbl proto-oncogene product (p120c-cbl) and in the upregulation of cytokine production. That various transmembrane signaling events were mediated by CD38 was demonstrated with CD38 knockout mice. In these mice, the ARC activity was dramatically decreased and, as a result, cADPr levels were decreased in all tissues examined with the exception of heart and brain. In pancreatic cells of the knockout mice, acetylcholine failed to trigger Ca^{2+} spikes since the agonist failed to activate cADPr production. CD38-deficient mice were also more susceptible to bacterial infections, as the failure to produce cADPr eventually prevented the Ca^{2+} -dependent migration of neutrophils to the infection sites. CD38 knockout female and male mice also showed marked defects in maternal nurturing and social behavior, respectively, suggesting that CD38 may be important in neurodevelopmental disorders.

Three isoforms of ARC have been cloned and characterized in sea urchin. One of them (SpARC1) is active in the lumen of the ER, indicating once again that messenger production may take place outside the cytosol. In contrast to SpARC1, heterologously expressed SpARC2 is localized to the plasma membrane as a glycosylphosphatidylinositol (GPI)-anchored plasma membrane protein. It has been speculated that SpARC2 could become internalized into the acidic endosomal system in which the base-exchange reaction is favored. As a result, SpARC2 could

preferentially catalyze the reaction that generates another second messenger, nicotinic acid adenine phosphate (NAADP), from a different substrate, NADP^+ . Conversely, the neutral luminal environment of SpARC1 would favor the cyclization reaction, thus predominantly promoting the synthesis of cADPr from NAD^+ . It must be mentioned that electron microscopy and immunogold labeling studies in sea urchin eggs have instead indicated that, in addition to the ectocellular isoform (ARC α), two other isoforms ARC β and ARC γ reside within the lumen of the acidic cortical granules that are responsible for the elevation of the fertilization envelope following egg activation.

Increasing evidence shows that CD38 may also reside in different subcellular compartments of many invertebrate and mammalian tissues. CD38 has been detected in the inner membrane of the nuclear envelope as a nonmembranous form of the enzyme that is linked to proteins involved in nuclear processes.

Analogues of cADPr have been synthesized, the first having amino (8-NH₂), azido (8-N₃), or bromo (8-Br) groups in the adenine ring. All three are competitive antagonists of cADPr-induced Ca^{2+} release in sea urchin egg homogenates. Being more potent, 8-NH₂-cADPr has become the reagent of choice to antagonize the effects of cADPr. As mentioned, unlike NAD^+ , NADP^+ induced Ca^{2+} release from egg homogenates without delay: in principle, then, no enzymatic conversion of NADP^+ appeared to be required. However, a simple alkaline treatment of NADP^+ greatly increased its activity to release Ca^{2+} , indicating that what is responsible for Ca^{2+} liberation might not be NADP^+ itself but its metabolic derivative. It was indeed shown that both CD38 and the *Aplysia* cyclase can take NADP^+ as a substrate and substitute its nicotinamide group with nicotinic acid to produce NAADP. Microinjection of NAADP into live eggs of sea urchin induced transient elevation of intracellular Ca^{2+} and triggered exocytosis of the cortical granules as InsP_3 would do. A unique property of the NAADP-sensitive Ca^{2+} release mechanism was its insensitivity to the antagonists of all the intracellular Ca^{2+} release channels ever known. However, subthreshold concentration of NAADP that does not itself release Ca^{2+} in sea urchin eggs prevented Ca^{2+} release in response to a second addition of NAADP. Likewise, extremely high concentration of NAADP does not release Ca^{2+} , suggesting that NAADP may bind to its receptor irreversibly. Another important point is that the NAADP-mediated Ca^{2+} release was not regulated by Ca^{2+} . However, it can still prime Ca^{2+} -induced Ca^{2+} release mechanisms through other Ca^{2+} channels. Early findings on such a cross-talk between NAADP and other intracellular Ca^{2+} channels were reported in pancreatic acinar cells, a popular cell model in the study of specific Ca^{2+} signals. In these cells, both neurotransmitter acetylcholine and the hormone cholecystokinin induce Ca^{2+} oscillations. However, those produced by the neurotransmitter are mediated by InsP_3 and Ca^{2+} , whereas those produced by the hormone are linked to the generation of cADPr and NAADP. It has been shown that NAADP acts at very low concentration and sensitizes cADPr and InsP_3 receptors.

cADPr- and NAADP-dependent Ca^{2+} Stores

Early evidence that the cADPr- and the NAADP-sensitive Ca^{2+} stores were physically distinct and separable from that of InsP_3 came from cell fractionation and cytoplasmic organelle

stratification of sea urchin eggs. Global photoactivation of the caged NAADP, injected into the stratified eggs, induced a localized pattern of Ca^{2+} . The NAADP-induced release occurred mainly in the pole distal to the nucleus, while the stores sensitive to cADPr localized to the nuclear pole and co-purified with ER markers in Percoll gradients. Uniform photo-activation of caged InsP_3 produced a pattern of Ca^{2+} mobilization that was similar to that of caged cADPr, but clearly distinct from that of NAADP. The identity of cytoplasmic organelle from which NAADP mobilized Ca^{2+} , which was evidently different from the ER, remained unknown for many years. Then, it was found that incubation of intact sea urchin eggs with glycyl-L-phenylalanine 2-naphthylamide (GPN), a substrate of the lysosomal exopeptidase cathepsin C which causes the loss of lysosome integrity, reduced the responsiveness to NAADP. The suggestion that NAADP could specifically mediate Ca^{2+} release from the acidic lysosomal compartment was further substantiated by the requirement of acidic environment for ARC to produce NAADP.

The implication of the lysosome studies is interesting, but the exact nature of the stores targeted by NAADP is still controversial. Several studies have, for instance, suggested that the ryanodine receptors (RyRs) in the ER could be a possible alternative candidate in a sense that the nuclei isolated from pancreatic cells are deprived of acidic organelles but still release Ca^{2+} from the nuclear envelope (that forms a continuity with the ER) when challenged with NAADP. In permeabilized pancreatic acinar cells, InsP_3 , cADPr, and NAADP can all release Ca^{2+} from the fraction of the ER located in the basal region, as well as from an acidic store in the secretory granular region at the opposite pole of the cell. It was claimed that the action of NAADP is dependent on ryanodine receptors operational in the ER. Thus, the NAADP-induced release from the acidic stores could be due to the extension of the ER into the regions containing the acidic granules. Further evidence suggesting the ER as the Ca^{2+} store targeted by NAADP comes from studies where NAADP releases Ca^{2+} from a thapsigargin-sensitive store, and from membranes incorporated into planar lipid bilayers. In the latter case, low concentrations of NAADP activated single-channel current with the characteristics of type 2 RyRs.

The extremely low level at which NAADP acts has complicated the measurements of its changes upon stimulation. Recent technological advances have made possible to detect both the basal levels of NAADP and its increases following cell stimulation in many cell types, including insulin-secreting pancreatic β -cells, human myometrical cells, and Jurkat cells. In sea urchin sperm, NAADP is rapidly synthesized upon exposure to the egg jelly coat and activates cation channels localized in the acrosome, a lysosome-related organelle involved in the formation of the acrosomal process.

cADPr-Mediated Ca^{2+} Signaling in Cells

The sea urchin eggs have been a popular system for studying Ca^{2+} mobilization since the intracellular Ca^{2+} stores express multiple Ca^{2+} release channels creating the fertilization Ca^{2+} wave. At sperm-egg interaction, a fast Ca^{2+} influx into the egg occurs as a result of the plasma membrane depolarization induced by the sperm (the cortical flash), which is followed

by an intracellular Ca^{2+} wave that propagates to the antipode of the egg. The rapid and transient increase in the intracellular concentration of cyclic guanosine monophosphate (cGMP) at fertilization, together with the finding that cGMP could mobilize Ca^{2+} in sea urchin eggs and homogenates supplemented with NAD^+ , suggested that ARC is activated by a cGMP-dependent protein kinase to produce cADPr, which in turn activates ryanodine receptor Ca^{2+} channels. This signaling pathway was further supported by the finding that nitric oxide (NO) could also evoke Ca^{2+} signals in sea urchin eggs through the activation of guanylyl cyclase. However, later work has suggested that the NO/cGMP/cADPr pathway may serve as a 'regulator' of the later phases of the Ca^{2+} transient at fertilization (see below), rather than as an 'activator' of the Ca^{2+} response. Thus, cADPr appears to play roles in both initiating and sustaining the Ca^{2+} response induced by the sperm.

It has also been shown that cADPr is generated in human pancreatic β -cells by glucose stimulation to mobilize Ca^{2+} from the ER in the process of insulin secretion. Interestingly, cADPr does not bind directly to the type 2 RyR expressed in rat pancreatic islets but acts on it through a mediator such as the FK506-binding protein 12.6. The binding of cADPr to FKBP12.6 causes the dissociation of the latter from the receptor, thereby increasing its Ca^{2+} -releasing channel activity. Hence, it was suggested that cADPr may serve as an endogenous modulator of Ca^{2+} -induced Ca^{2+} release (CICR) which is a key property of RyRs.

cADPr and NAADP at Fertilization

The fertilization of eggs from invertebrates to mammals is accompanied by single or repetitive Ca^{2+} transients. The transient increase of Ca^{2+} propagates across the egg as a Ca^{2+} wave, which is necessary for the egg. As mentioned, the global Ca^{2+} wave is preceded by the cortical flash which is produced by Ca^{2+} influx through voltage-gated channels activated by sperm-induced depolarization of the egg plasma membrane (Figure 1). The proposal that the InsP_3 pathway is responsible for the generation or propagation of Ca^{2+} transients has gained general support on a number of findings: microinjection of InsP_3 into eggs induces a Ca^{2+} elevation accompanied by the increase of phosphoinositide metabolism immediately after fertilization. In eggs preloaded with heparin, a potent competitive inhibitor of the InsP_3 -induced Ca^{2+} release, the Ca^{2+} transient of fertilization was delayed and reduced in both velocity and amplitude. Furthermore, intracellular injection of the tandem Src Homology 2 (SH2) domains of bovine

phospholipase $\text{C}\gamma$ (PLC γ) produced a concentration-dependent inhibition of the Ca^{2+} release. In addition, cADPr is as effective as InsP_3 in liberating Ca^{2+} from the intracellular stores of sea urchin eggs. Sea urchin microsomes respond to cADPr even after their desensitization to a high concentration of InsP_3 , demonstrating that a distinct cADPr-linked Ca^{2+} mobilization mechanism exists in these eggs. The cADPr-sensitive Ca^{2+} release is independent of InsP_3 , as it was insensitive to heparin. The cADPr-sensitive Ca^{2+} release mechanism critically depends on calmodulin (CaM). Sea urchin microsomes do not respond to cADPr even at concentrations as high as 100 μM , but CaM restores their sensitivity to nanomolar concentrations of cADPr. At fertilization, cADPr thus acts synergistically with InsP_3 to sustain the intracellular Ca^{2+} wave. It has recently been shown that cADPr is also synthesized in the lumen of the acidic exocytotic vesicles (cortical granules) located beneath the plasma membrane, where it provides local Ca^{2+} signals to drive exocytosis. On the other hand, cADPr shuttled into cytosol through a separate cADPr transporter contributes to the formation of a global Ca^{2+} wave.

As discussed above, NO is also involved in the Ca^{2+} swings during the initial and later phases of the sperm-induced Ca^{2+} response. NO is produced in the sperm undergoing acrosome reaction and in the eggs during fertilization. NO would stimulate the production of cGMP and activates ARC to produce cADPr. However, the precise temporal relationship between the rises of NO and the Ca^{2+} transient was not fully resolved. As the enzyme synthesizing NO is also activated by Ca^{2+} , it appeared that the main role of the NO/cGMP/cADPr pathway was to sustain the later phase of Ca^{2+} transient during the fertilization of sea urchin eggs. However, the fertilization-induced increase in cGMP was also observed to precede the explosive Ca^{2+} elevation in other species of sea urchin eggs. Hence, the controversy remains to be resolved, although it is possible that cGMP production could be localized strictly around the sperm entry site and induce a local Ca^{2+} increase by the production of cADPr.

As mentioned, the RyR complex is the target of cADPr. RyR antagonists such as ruthenium red, Mg^{2+} , and procaine were shown to inhibit the cADPr-induced Ca^{2+} release, while the agonists of the CICR such as caffeine, Ca^{2+} , and Sr^{2+} potentiated the effect. In mouse eggs, activation of the cADPr/ryanodine pathway induced the conversion of the zona pellucida glycoprotein ZP2 to its postfertilization form ZP2f. However, the treatment of the eggs that would block the release of Ca^{2+} from the ryanodine-sensitive store had no effect on egg activation following fertilization. Thus, the release of Ca^{2+} from RyRs is not essential for sperm-induced egg activation.

Figure 1 Spatio-temporal changes of the fertilization-induced Ca^{2+} signals in mature eggs of starfish. The first image shows the Ca^{2+} release in the cortex of the cell (cortical flash). This is followed by the traversing Ca^{2+} wave that spreads from the site of sperm-egg interaction (arrow) to the cytoplasm of the opposite side of the egg. Ca^{2+} changes were monitored with the Ca^{2+} indicator, calcium green dextran 10 000 MW. The Ca^{2+} increase was monitored by employing a cooled CCD camera, and the relative fluorescence images were presented at different time points after sperm-egg contact.

It nevertheless has an important role: it modulates the recharge stage of the ER Ca^{2+} store. In *Xenopus* oocytes lacking the RyR system, photoliberation of caged InsP_3 following the injection of the nonmetabolizable analog 3-deaza-cADPr strongly potentiated the Ca^{2+} response.

Microinjection of NAADP into live sea urchin eggs also induces a large transient increase of intracellular Ca^{2+} . The injected egg, however, became desensitized to NAADP, that is, they failed to respond to a second injection of NAADP. The Ca^{2+} release induced by NAADP is kinetically faster than that induced by cADPr or InsP_3 and insensitive to 8-NH₂cADPr or heparin. Thus, the NAADP-linked mechanism is independent of cADPr or InsP_3 . Conversely, in microsomes desensitized by subthreshold concentrations of NAADP, both cADPr and InsP_3 can still induce Ca^{2+} release.

Ca^{2+} Response to cADPr and NAADP in Starfish Eggs

Starfish oocytes have contributed important information to the understanding of the Ca^{2+} signaling induced by cADPr and NAADP. Being arrested at prophase I of meiosis, immature oocytes of starfish are characterized by the presence a large nucleus (up to 60 μm in diameter). With the use of the hormone, 1-methyladenine (1-MA), the spatiotemporal pattern of cADPr- and NAADP-promoted Ca^{2+} release can be studied during the maturation process.

The induction of the maturation process by 1-MA induces profound changes in the oocytes along with the increased sensitivity of the Ca^{2+} stores to InsP_3 . This is more evident in the perinuclear area near the animal hemisphere, as ultraviolet (UV) irradiation of fully diffused caged InsP_3 starts to release Ca^{2+} specifically in these areas before the Ca^{2+} wave propagates to the entire oocyte along the animal/vegetal axis.

Maturation also enhances the eggs' Ca^{2+} response to cADPr. The photoactivation of the same amount of caged cADPr induces a higher Ca^{2+} increase in the eggs matured with 1-MA. The Ca^{2+} signal starts at one or two circumscribed sites in the cortex, and expands to a cortical flash and then spreads centripetally to the remainder of the cell. The cortical flash is probably linked to Ca^{2+} influx from the extracellular medium, as it is blocked when the cADPr was uncaged in the eggs washed several times in CaFSW. The cADPr-induced Ca^{2+} responses thus closely resemble those induced by the sperm. However, the physiological role of cADPr-dependent Ca^{2+} signaling at fertilization is still questionable. Although *Astropecten arancia-cus* eggs respond to microinjected cADPr with Ca^{2+} release, starfish eggs of other species, for example, *Asterina pectinifera*, did not display the same response. Furthermore, pre-injection of 8-NH₂cADPr into mature eggs blocks the cADPr-induced Ca^{2+} increase but not the one induced by the sperm, indicating that this second messenger may not play an essential role in shaping the Ca^{2+} waves at fertilization.

Determination of the precise spatial distribution of the NAADP-induced Ca^{2+} signals in starfish eggs also contributed to the understanding of the mechanisms underlying the sperm-induced Ca^{2+} increase at fertilization. The photoliberation of caged NAADP into immature and mature eggs induces a cortical Ca^{2+} increase that spreads throughout the cytoplasm as a wave due to the amplification of the signals by the InsP_3 and ryanodine receptors through the CICR mechanism (Figure 2(a)). The uncaging of NAADP in CFSW failed to promote the Ca^{2+} response. Suggesting its involvement of Ca^{2+} influx, the NAADP-induced Ca^{2+} signal was shown to be inhibited by SK&F 96365, an inhibitor of receptor-operated calcium entry, and by the L-type calcium channel blocker verapamil. The NAADP-elicited Ca^{2+} influx is the result of the activation of a cationic membrane current requiring both an initial

Figure 2 Ca^{2+} influx induced by NAADP in matured eggs of starfish. (a) The global photoliberation of pre-injected caged NAADP induces a Ca^{2+} response that occurs in the cortical region of the egg and spreads subsequently to the center of the cell. (b) The NAADP-elicited Ca^{2+} influx is associated with a membrane current. Removal of extracellular Ca^{2+} abolishes the current, whereas the replacement of external Na^+ with an equimolar amount of choline does not affect it. (c) The NAADP-linked Ca^{2+} release promotes the elevation of the vitelline envelope (arrow).

submembrane Ca^{2+} pulse and NAADP (Figure 2(b)). It was also suggested that NAADP might trigger a highly localized cortical Ca^{2+} increase from a thapsigargin-sensitive store that would be tightly coupled to the NAADP-dependent membrane channels, raising the possibility that NAADP could play an important role in the initiation of the Ca^{2+} response at fertilization. The finding that the changes in membrane potential induced by the sperm were similar to that induced by NAADP supports the suggestion. This triggering role has also been supported by experiments on immature oocytes from which the nucleus had been removed before the induction of maturation by 1-MA. The removal of the nucleus does not affect the initial cortical Ca^{2+} response by NAADP or by the sperm but blocks the globalization of the Ca^{2+} wave which is due to InsP_3 . Subsequent work has shown that NAADP also activates Ca^{2+} influx in sea urchin eggs. The desensitization of the eggs by pretreatment with NAADP strongly reduced the cortical flash and the subsequent generation of the Ca^{2+} wave at fertilization, indicating that NAADP is involved in sperm-induced Ca^{2+} signaling and activation of the eggs. The source of NAADP that acts on the egg activation remains obscure, but the presence of a large amount (5 μM) of NAADP sea urchin sperm suggests a possibility of direct transfer from the sperm. In sea urchin eggs, NAADP has been proposed to mobilize Ca^{2+} from lysosome-like acidic stores, but the phenomenon was not confirmed in starfish eggs. As echinoderm, the cortical distribution of lysosomes in starfish eggs (Figure 3) was similar and suggestive of their involvement in the NAADP-elicited Ca^{2+} release. However, drugs disrupting the acidic compartments failed to affect

the NAADP-induced depolarization and cortical Ca^{2+} release, indicating that lysosomes are probably not the NAADP target in starfish eggs.

Identification of TPCs as NAADP Receptors

The search for the molecular identity of NAADP receptors has been, and still is, difficult. The putative NAADP receptors have been solubilized from sea urchin homogenates and were shown to bind their ligand with appropriate affinity and selectivity. NAADP binding was not affected by luminal or cytosolic Ca^{2+} concentrations and showed little dependence on pH. Furthermore, the binding of NAADP was apparently irreversible, as no displacement of bound ^{32}P -NAADP by unlabeled NAADP was observed. The binding depends on K^+ and is not observed when the latter was replaced by Na^+ in the buffer. Following the finding that NAADP targets lysosome-like acidic stores, it was suggested that the mammalian ion channel activated by NAADP to produce a local Ca^{2+} burst from lysosomes could be the transient receptor potential-mucolipin 1 channel (TRP-ML1), which was found to be associated with lysosomes in coronary arterial myocytes. Consistent with this suggestion, a TRP-ML1 antibody blocked NAADP-sensitive Ca^{2+} release from lysosome membranes, purified from the rat liver and coronary arterial myocytes. Silencing TRP-ML1 expression also diminished lysosome-associated Ca^{2+} release in the myocytes. On the other hand, other evidence has been provided that NAADP mobilizes Ca^{2+} from acidic organelle stores through the activation of a family of ion channels known as TPCs, which are new members of the voltage-gated cation channel superfamily. Comparative genomic analysis indicates the presence of up to three family members of these channels in sea urchin and most vertebrate species. In plants, it was suggested that TPC plays a critical role in regulating Ca^{2+} -linked physiological processes essential for resistance and adaptation to environmental stresses. The TPC protein contains 12 putative transmembrane segments that can be divided into two six-transmembrane homologous domains, each containing a pore loop. The cytoplasmic side of the endolysosomal membranes contains the amino and carboxyl termini as well as the large intermediate loop. The molecular cloning of all three sea urchin TPC isoforms that are targeted to acidic vesicles has supported the proposal of NAADP-dependent calcium release from acidic calcium stores. First, NAADP binds TPC2 at high- and low-affinity sites and thereby induces calcium release and homologous desensitization, as was expected from the studies of the then unknown endogenous NAADP receptors. Second, NAADP-evoked calcium signals via TPC2 are ablated by silencing TPC2, and by depletion of acidic calcium stores with bafilomycin A1. Interestingly, NAADP-induced Ca^{2+} signals are biphasic in their pattern. The initial phase of Ca^{2+} release from lysosomes via TPC2 channel is subsequently amplified by CICR from the ER. By contrast, Ca^{2+} release via endosome-expressed TPC1 induces only a spatially restricted quantal vesicular Ca^{2+} release that is not amplified by CICR. In line with this, TPC1 in *Arabidopsis thaliana* is also localized in the vacuolar membrane of guard cells to form a Ca^{2+} release channel. It plays an important role in regulating Ca^{2+} -induced stomatal closure, which is necessary to reduce water loss in response to a variety of external and

Figure 3 Distribution of acidic organelles labeled by the injection of Lyso-Tracker Red in starfish eggs. (a) The lysosomal dye visualizes a thick layer of vesicles in the cortical domain of immature starfish oocytes (not treated with 1-MA). internal stimuli such as light, CO₂, drought, pathogen attack, and plant hormones. Anti-TPC antibodies and organelle markers have shown that TPCs are expressed intracellularly, and specifically targeted to lysosomal membranes. Overexpression of TPC2 gave rise to much higher biphasic Ca²⁺ release in response to uncaged NAADP in the cells that would normally respond with a short-lived small Ca²⁺ signal. This observation is also consistent with the idea that lysosomes play a role in mediating the NAADP-dependent Ca²⁺ release.

Conclusions

The nature of the Ca²⁺-releasing functions of cADPr and NAADP has been characterized, in major part, from the studies on the eggs and fertilization. For that reason, much emphasis was placed on the sperm-egg interaction in this article. However, the two messengers are likely to have more physiological significance in other cell types. For instance, it has been shown that NAADP takes temporal primacy over the well-known InsP₃ route during the Ca²⁺ response induced by activators of mammalian pancreatic acinar cells. In the sperm-egg system, the initial and localized Ca²⁺ response might be induced by NAADP through the initial activation of plasma membrane cationic channels in both the sperm and the egg at fertilization.

The initial local response is followed by the globalization of the Ca²⁺ signal through the activation of specific receptors of InsP₃ and cADPr in the egg. This response is dramatically amplified by the CICR process. Hence, the cross-talk between the signaling systems involving different second messengers may contribute to diversify the ways to fine-tune the Ca²⁺ response in cells.

Glossary

A-kinase anchoring protein (AKAP)79/150 It constitutes a scaffold of cAMP-dependent protein kinase, protein kinase C, and calcineurin. The colocalization of these three enzymes with their respective substrates insures the coordination of their phosphorylation pathways.

Calmodulin A unique member of a class of calcium-binding proteins that acts as sensors of changes in intracellular concentration of calcium induced by external signals. It modulates the activity of a large number of enzymes involved in the regulation of cellular processes particularly those involved in

protein phosphorylation, and in cyclic adenosine monophosphate (cAMP) synthesis and degradation.

EF-Hand Structural motif composed of 30 contiguous amino acids forming two helices joined by a Ca^{2+} -binding loop.

Immunosuppressive drugs (FK506 and cyclosporin A (CsA)) Fungal natural products used to prevent organ rejection after organ transplant operation and treatment of autoimmune diseases.

Regulators of calcineurin (RCANs) A family of endogenous protein inhibitors of calcineurin expressed in different tissues and organisms. They modulate calcineurin activity acting as feedback inhibitors.

Subunit Structure and Isoforms

Calcineurin is a heterodimer of a 58–64-kDa catalytic subunit, calcineurin A (CnA), tightly bound, even in the presence of ethylene glycol tetraacetic acid (EGTA), to a 19-kDa Ca^{2+} -binding regulatory subunit, calcineurin B (CnB). This subunit structure, unique among protein phosphatases, is conserved in all eukaryotes. Three mammalian isoforms (α , β , and γ) of CnA have been identified at the messenger RNA (mRNA) level. The corresponding human genes (PPP3CA, PPP3CB, and PPP3CC) are located on human chromosomes 4, 10, and 8 respectively. Additional isoforms, products of alternative splicing, have been detected at the mRNA level. Two mammalian isoforms of CnB, CnB1 and CnB2 (expressed essentially in testis), are the products of two genes (PPP3R1) located on chromosome 2 and (PPP3R2) located on chromosome 9. Although expressed in most, if not all, tissues, calcineurin is particularly abundant in the brain where the α -isoform of CnA is predominant. The β -isoform is broadly distributed while the γ -isoform is expressed essentially in the testis. Calcineurin has been identified in all eukaryotes, including fungi, and the budding yeast *Saccharomyces cerevisiae*. In plants, no calcineurin A has been identified, and calcineurin B-like proteins (CBLs) specifically interact with a family of CBL-interacting kinases (CIPKs).

Structure

The domain structure of calcineurin is equally well conserved. In all species, the catalytic domain located in the N-terminal of two-thirds of CnA, is followed by a CnB-binding domain. The C-terminal regulatory domain contains a CaM-binding and an autoinhibitory domain. In the absence of CaM, the native protein has a very low activity. The catalytic and CnB-binding domains, severed from the regulatory domain by limited proteolysis, constitute the Ca^{2+} -independent truncated form of

calcineurin routinely used in overexpression experiments. CnB is an EF-hand Ca^{2+} -binding protein of the CaM family. It binds four moles of Ca^{2+} , two with high affinity ($k_d < 10^{-7}\text{M}$) and two with moderate affinity in the micromolar range. The N-terminal glycine of CnB is myristoylated. This perfectly conserved posttranslational modification of CnB, apparently not involved in membrane association or required for enzymatic activity, may serve as a stabilizing structural element.

The crystal structure of the recombinant α -isoform of human calcineurin expressed in *Escherichia coli* is illustrated in **Figure 1(a)**. The architecture of the catalytic domain is similar to those of protein phosphatases γ -1 and γ -2A. It consists of a β -sandwich surrounded on one side by seven α -helices and on the other side by a mixed α/β structure. The catalytic site contains an Fe^{2+} – Zn^{2+} dinuclear metal center. The catalytic domain extends into a five-turn amphipathic α -helix whose top face is covered by a 33-Å groove formed by the N- and C-terminal lobes and the C-terminal strand of CnB. A short helical segment blocks the catalytic center. With the exception of this segment, the C-terminal regulatory domain, not visible in the electron density map, is flexible and highly sensitive to proteolytic attack in the absence of CaM. The crystal structure of the proteolytic derivative of bovine calcineurin, lacking the regulatory domain, bound to FK506/FK506-Binding Protein12 (FKBP12), illustrated in **Figure 1(b)**, is similar to that of the full-length protein. The bottom face of the CnB-binding helix of CnA and CnB forms the site of interaction with the FKBP–FK506 and CsA–CyPA complexes. The key role of CnB in forming the drug-binding site provides a molecular basis for the specificity of FK506 and CsA as calcineurin inhibitors.

Enzymatic Properties

Ca^{2+} /CaM-Dependent Stimulation

Calcineurin is a protein phosphatase with a binuclear iron–zinc active center. The purified enzyme, partially depleted of

its metal cofactors, is activated by exogenous metal ions (0.1 mM Mn²⁺ or more than 6 mM Mg²⁺). Purified calcineurin, which has retained stoichiometric amounts of Fe³⁺ and Zn²⁺, is inactive and not activated by exogenous metal ions. Activation requires treatment under anaerobic conditions with the reducing agent, ascorbate which converts Fe³⁺ to Fe²⁺. Its phosphatase activity does not require exogenous metal ions. Regardless of its metal content, the phosphatase activity of calcineurin is dependent on the presence of Ca²⁺ and CaM. A small activation is observed upon addition of Ca²⁺ ($K_{act} = 0.5 \mu\text{M}$). Addition of the CaM results in a 50–100-fold increase of the V_{max} without affecting the value of the K_m . The highly cooperative stimulation of the enzyme by CaM (Hill coefficient of 2.5–3) allows calcineurin to respond to narrow Ca²⁺ thresholds following cell stimulation. Because of its high affinity for CaM ($K_{act} \leq 10^{-10} \text{ M}$), the activation of calcineurin in response to a Ca²⁺ signal can precede the activation of all known CaM-regulated kinases.

Enzymatic Assays

A 19-residue synthetic peptide containing the phosphorylation site of the RII subunit of cyclic adenosine monophosphate (cAMP)-dependent protein kinase (PKA) and *p*-nitrophenyl-phosphate are routinely used to measure the phosphatase activity of calcineurin. In crude tissue extracts, calcineurin activity is distinguished from that of other neutral serine-threonine protein phosphatases by its (1) Ca²⁺ dependence; (2) inhibition by CaM-binding peptides and inhibitors; (3) resistance to the inhibitors of protein phosphatases –1 and –2A (Inhibitor-1, DARPP32, Inhibitor-2, okadaic acid, microcystin, and calyculin); and (4) specific inhibition of its protein phosphatase activity by FK506 (but not rapamycin) and CsA in the presence of saturating amounts of their respective binding proteins, FKBP12 and CypA. The *p*-nitrophenyl-phosphate activity of calcineurin, stimulated by FK506 and CsA, cannot be used to measure calcineurin activity in crude extracts. Unlike protein phosphatase-2 C, which requires Mg²⁺ for activity, calcineurin that has retained its natural metal cofactors does not require Mg²⁺.

Substrate Specificity

Calcineurin is a dual protein phosphatase. It dephosphorylates both phosphoserine/threonine and phosphotyrosine peptides. Peptides with a basic residue on the N-terminal side of the phosphorylated amino acid and lacking acidic residue of the C-terminal side are preferentially dephosphorylated by calcineurin. In addition to the recognition of the sequence surrounding the phosphorylated residues, the substrate specificity of calcineurin also depends on the presence of a calcineurin-binding motif, LxVP, which was previously identified in the sequence of a major substrate of calcineurin, the transcription factor, nuclear factor of activated T cells (NFAT). This motif is also present in most other calcineurin substrates. Its presence greatly decreases the K_m values, and LxVP peptides act as competitive inhibitors of calcineurin toward most of its substrates. The presence of an additional aromatic residue at the N-terminus greatly decreases the K_i value.

The calcineurin-binding site of this motif has recently been shown to overlap with the binding site of the immunosuppressive drugs bound to their binding proteins. The transcription factor NFAT also contains another calcineurin-binding motif, PxlIT, responsible for its Ca^{2+} -dependent and phosphorylation-independent anchoring to calcineurin. The anchoring of NFAT allows its dephosphorylation, despite its low intracellular concentration, and the nuclear cotranslocation of calcineurin and NFAT. The crystal structure of human recombinant-truncated calcineurin complexed with the peptide ligand, PVI-VIT, closely related to the docking sequence PxlIT of NFAT3 and NFAT4 anchoring NFAT to calcineurin is shown in [Figure 1 \(c\)](#). PVI-VIT adds as a β strand along the edge of the calcineurin constituted by the strands β 11 and β 14, away from the catalytic center. This peptide prevents NFAT activation but does inhibit calcineurin-mediated dephosphorylation of the RII peptide.

Regulation

Ca^{2+} Regulation

Two structurally similar but functionally different Ca^{2+} -binding proteins, CaM and CnB, mediate the Ca^{2+} regulation of calcineurin. CnB is tightly bound to CnA even in the absence of Ca^{2+} and plays both structural and functional roles. It is required to confer enzymatic activity to the catalytic subunit. The recombinant α - and β -isoforms of CnA expressed in bacteria and SF9 cells require CnB for activity. Ca^{2+} binding to CnB is required for the interaction of calcineurin with the immunosuppressive drugs bound to their respective binding proteins.

Ca^{2+} -dependent binding of CaM to calcineurin induces a conformational change of the regulatory domain accompanied by the displacement of the autoinhibitory domain. The resulting exposure of the catalytic center is sufficient to activate the *p*-nitrophenylphosphatase activity of calcineurin but not its protein phosphatase activity.

Activation of the latter requires CaM binding to the CaM-binding domain to prevent inhibition of calcineurin by the CaM-binding domain. Prolonged exposure of the catalytic center facilitates the oxidation of Fe^{2+} and results in inactivation of calcineurin that is prevented by superoxide dismutase and reversed by ascorbate. Thus, CaM can both activate and inactivate calcineurin depending on the length of the Ca^{2+} signal. The CaM-dependent oxidation of Fe^{2+} and inactivation of calcineurin is a potential mechanism to regulate its activity during oxidative stress.

Endogenous Regulatory Proteins

Endogenous regulatory proteins, whose expression varies from tissue to tissue, modulate the activity of calcineurin *in vivo*. A family of 22–24-kDa proteins, regulators of calcineurin (RCANs), identified in both yeast and mammalian cells acts as feedback inhibitors of calcineurin. The mammalian proteins are identical to proteins encoded in the Down's syndrome critical region 1 (DSCR1) gene (ZAK1-4, DSCRIL1, and DSCRIL). The expression of these proteins is upregulated by a calcineurin/NFAT-dependent mechanism. RCANs inhibit both calcineurin expression and activity. These proteins can interact with calcineurin through multiple interaction sites. Two sites

are located in exon 7 of RCAN, a PxlIT motif similar to the PxlIT motif found in NFAT and an ELHA motif. Another highly conserved serine–proline motif (FLSPP) is similar to sequences found in calcineurin substrates. The interaction of RCANs with calcineurin does not require, but is facilitated by, the presence of Ca^{2+} and CaM. Phosphorylation of RCANs by GSK3 prevents their inhibitory activity suggesting that *in vivo*, depending on their phosphorylation state, RCANs could act as activators as well as inhibitors of calcineurin.

A 240-kDa nuclear protein, Cain/Cabin1, has been identified as a noncompetitive inhibitor of calcineurin. Binding of Cabin1 to calcineurin requires Ca^{2+} and protein kinase C (PKC) activation and is inhibited by FK506/FKBP, suggesting that it binds at the drug-interacting site. A basic domain in the C-terminus of Cabin1 has been identified as the calcineurin-binding site. A third group of proteins, including the PKA scaffold protein, AKAP79 in brain, and calsarcins in skeletal and cardiac muscles may serve to anchor calcineurin to its site of action.

Functions

Regulation of Gene Expression

The elucidation of the Ca^{2+} /calcineurin/NFAT transduction pathway leading to T-cell activation opened the way to uncover the important role of calcineurin in the regulation of gene expression in many other cell types. As illustrated in [Figure 2](#), in T cells, the release of Ca^{2+} from the inositol triphosphate (IP_3)-sensitive stores, following occupancy of the T-cell receptor, activates calcineurin which dephosphorylates the transcription factor NFAT. Dephosphorylation of NFAT is accompanied by the exposure of a nuclear localization signal and translocation of NFAT to the nucleus. Calcineurin, anchored to NFAT through an anchoring domain (PxlIT), is translocated to the nucleus with NFAT. Dephosphorylation of NFAT results not only in its nuclear translocation but also in enhancement of DNA binding and transcriptional activity that is also dependent on the activation of the Ras/PKC pathway. Nuclear export depends on NFAT rephosphorylation upon removal of Ca^{2+} and calcineurin inactivation. Several kinases, including glycogen synthase kinase -3 (GSK3) and casein kinase 1, have been implicated in this process.

Four NFAT isoforms (NFAT1–4) are expressed in many tissues. These isoforms share a highly conserved N-terminal regulatory domain, composed of two calcineurin-binding motifs, multiple phosphorylation sites, and a nuclear localization signal. The two calcineurin-binding motifs bind calcineurin with an affinity in the micro-molar range. In skeletal muscle, calcineurin-mediated dephosphorylation of the transcription factors, NFAT-3 and the myogenic enhancing factor (MEF2), play a crucial role in the switch from fast to slow oxidative fibers induced by sustained tonic contraction. In the heart, the calcineurin-mediated activation of NFAT3 and MEF2D, in conjunction with the cardiac-specific transcription factor GATA4, has been implicated in the development of cardiac hypertrophy in response to stress. Transgenic mice lacking the β -isoform of calcineurin (the predominant isoform in heart) have impaired ability to develop cardiac hypertrophy in response to hypertrophic agonists while severe hypertrophy

Figure 2 Calcineurin-mediated signal transduction from the T-cell receptor to the nucleus leading to the induction of the cytokine genes (IL-2, -3, -4), granulocyte-macrophage stimulating factor (GM-CSF), and tumor necrosis factor (TNF- α). Gene activation requires the concomitant activation of the ras/PKC pathway. Reproduced from Klee C, Wang X, and Ren H (1999) Calcium-regulated protein dephosphorylation. In: Carafoli E and Klee C (eds.) *Calcium as a Cellular Regulator*, pp. 344–370. New York: Oxford University Press.

and cardiac heart failure is induced by overexpression of the constitutively active calcineurin. The calcineurin/NFAT pathway is essential for the development of heart valves and the vascular developmental pattern during embryogenesis. In the brain, Ca^{2+} homeostasis is itself regulated by calcineurin. Activation of NFAT increases the expression of the IP_3 receptors, the plasma membrane Ca^{2+} pumps, and the Ca^{2+} exchanger. The increasing number of genes whose expression is induced by NFAT indicates a potential role of calcineurin in the regulation of gene expression during cell differentiation and apoptosis.

The importance of calcineurin in the regulation of these cellular processes and its involvement in the pathogenesis of many diseases based on overexpression and knockout models is well documented. To fully assess the contribution of calcineurin in the transduction of so many diverse signals, we must understand how different pathways interact with each other. In budding yeast, the calcineurin-mediated dephosphorylation of a transcription factor (Crz1p/Tcn1p) plays a major role in the regulation of genes involved in ion homeostasis. The mechanism is similar to NFAT-mediated transcriptional control in

mammalian cells. In yeast, genetic analysis adds strong support to the physiological significance of this calcineurin signaling pathway in response to exposure to abnormal concentrations of ions or prolonged exposure to mating pheromones. It not only illustrates the important role of calcineurin in the regulation of gene expression, but also reveals the participation of many other factors in this complex signaling pathway.

Neuronal Functions

Calcineurin is 1% of the total protein and broadly distributed in brain. There are few neuronal functions which are not modulated by calcineurin. A major role of calcineurin in brain is to trigger a protein phosphatase cascade initiated by the dephosphorylation of two other major substrates of calcineurin, the endogenous inhibitors of protein phosphatase-1, Inhibitor-1, and dopamine and cAMP-regulated neuronal phosphoprotein of 32 kDa (DARPP32). This cascade counteracts the stimulatory effects of cAMP and Ca^{2+} -regulated kinases. It explains the antagonistic effects of Ca^{2+} release induced by glutamate binding to the NMDA receptor and dopamine binding to some dopamine receptors in striatal neurons. Whether it activates protein phosphatase-1 or dephosphorylates an increasing number of specific substrates, calcineurin has been implicated in the regulation of neuronal processes as diverse as the expression and activity of ion channels, the synthesis of nitric oxide, the release of neurotransmitters, synaptic vesicle recycling, and neurite outgrowth. Calcineurin inhibitors and transgenic animals lacking the calcineurin genes or overexpressing the constitutive form of calcineurin have been widely used to study the involvement of calcineurin in the storage of long and short memory. How calcineurin and other protein kinases and phosphatases affect learning and memory remains one of the most challenging problems in neurobiology.

Glossary

Calmodulin Calcium-binding protein that binds to target enzymes in a Ca^{2+} -dependent manner and activates their function.

Nitric oxide Diatomic free radical that is generated from L-arginine by the nitric oxide (NO) synthases and is widely active in numerous processes in biology.

Reductase domain Flavoprotein domain of NO synthases that contains bound flavin adenine dinucleotide and flavin mononucleotide and is responsible for transferring electrons from nicotinamide adenine dinucleotide phosphate to the heme group in NO synthase.

Nitric oxide (NO) is an important signal and effector molecule in animal physiology. NO is generated from L-arginine by the NO synthases (NOSs). Three NOSs have been characterized in animals: neuronal NOS (nNOS, type I), cytokine-inducible NOS (iNOS, type II), and endothelial NOS (eNOS, type III). Importantly, the activities of all three depend on their binding calmodulin (CaM). CaM binds reversibly to eNOS and nNOS in response to elevated Ca^{2+} concentrations and so their activities are regulated by intracellular Ca^{2+} . By contrast, iNOS binds CaM independent of Ca^{2+} concentrations and is therefore continuously active after it is expressed. Because it is unusual for a redox enzyme like NOS to be controlled by a Ca^{2+} -binding protein, the NOS–CaM interaction has provided new insight into some aspects of protein structure and function.

NO Synthases

To become active, each NOS enzyme must assemble into a dimer of two subunits. Each subunit in the NOS dimer contains an N-terminal oxygenase domain that binds iron protoporphyrin IX (heme), the cofactor 6R-tetrahydrobiopterin (H_4B), and the substrate Arg, and a C-terminal reductase domain that binds flavin mononucleotide (FMN), flavin adenine dinucleotide (FAD), and nicotinamide adenine dinucleotide phosphate (NADPH). Between oxygenase and reductase domains, there is a 20–25-amino-acid CaM-binding motif (Figure 1).

NO synthesis depends on electron transfer to the heme, and this process only occurs when CaM is bound. In a CaM-bound NOS dimer, the electrons from NADPH load into the FAD and FMN groups in one subunit, and then transfer from the FMN to the heme that is located in the partner subunit (Figure 1). In general, CaM activates electron transfer in NOS at two points: electron transfer into the flavins (intradomain) and between the FMN and heme (interdomain). Intradomain transfer is associated with enhanced catalysis by the NOS reductase domain, as measured by rates of NADPH-dependent ferricyanide or cytochrome *c* (Cyt *c*) reduction. CaM activation of the interdomain

electron transfer in NOS results in reduction of the ferric heme iron, which is a prerequisite for oxygen binding to the heme and for NO synthesis.

Calmodulin Interactions with Ca^{2+} and with NOS

CaM is a small Ca^{2+} -binding protein (molecular weight 17 kDa) consisting of two similar globular lobes connected by a central linker region. Each lobe contains two E–F hands which include an N-terminal helix (E helix), a centrally located Ca^{2+} coordinating loop, and a C-terminal helix (F helix) (domains of CaM are generally labeled as 1–4 from N to C terminal). Upon Ca^{2+} binding, CaM is able to bind to and activate more than 30 target enzymes, enabling it to regulate numerous second messengers and cell functions. Binding and full activation of target proteins by CaM typically requires occupancy of all four Ca^{2+} -binding sites in CaM. The carboxy-terminal lobe contains two high-affinity Ca^{2+} -binding sites, while the amino-terminal lobe contains two sites with lower Ca^{2+} affinity. Conformational changes occur in CaM after it binds Ca^{2+} : hydrophobic surface residues become exposed in order to form crucial van der Waals interactions with the hydrophobic face of the target peptide recognition site.

CaM binds to each NOS subunit in a 1:1 stoichiometry with reasonably high affinity. Binding affinity studies with peptides that correspond to NOS CaM recognition sequences show that the three NOSs display different affinities toward CaM with the general order being cytokine-inducible NOS (iNOS) $\gg$ neuronal NOS (nNOS) $\approx$ endothelial NOS (eNOS). The iNOS peptide binds well to CaM both in the presence and absence of Ca^{2+} , but eNOS and nNOS peptides bind to the CaM only in the presence of Ca^{2+} .

Each lobe of CaM binds to NOS independently and displays different affinities toward NOS. The CaM–nNOS interaction has been investigated using CaM mutants and plant CaM proteins. nNOS displays a high degree of structural specificity toward CaM domains 1, 3, and possibly 4 regarding activation of heme reduction and NO synthesis. The CaM–nNOS interactions are particularly important for electron transfer and involve the latch region of CaM (formed by CaM domains 1 and 3) and a methionine

Figure 1 CaM-induced electron transfer in nNOS. CaM binding in response to elevated Ca^{2+} concentrations enables electron transfer between FMN and the heme located in adjacent subunits of the NOS dimer.

residue in domain 4. These regions of CaM appear to interact with as yet unknown regions on nNOS that are distinct from its canonical CaM-binding sequence. The charge and length of the central linker are also found to affect the binding and activation of iNOS through electrostatic interaction in the central linker and hydrophobic interactions in the globular domain of CaM, which seems responsible for its tight association to the iNOS. Ca^{2+} dissociation from NOS-bound CaM occurs in two sequential steps: rapid Ca^{2+} dissociation from the N-terminal lobe occurs first and corresponds with inactivation of NO synthesis, followed by a slower Ca^{2+} dissociation from the C-terminal lobe, which leads to the dissociation of CaM from NOS. Conformational changes occur in the NOS CaM-binding peptides when they bind CaM. Typically, the peptides acquire an α -helical conformation upon interaction with Ca^{2+} bound CaM. A CaM-induced conformational change in the NOS reductase domain also occurs as indicated by changes in protein and flavin fluorescence and by a change in the trypsin proteolysis pattern.

A crystallographic structure of Ca^{2+} -loaded CaM bound to a 20-residue peptide corresponding to the eNOS CaM recognition sequence is available. The structure revealed that the α -helical eNOS peptide binds to CaM in an antiparallel orientation through extensive hydrophobic interactions: the N-terminal and C-terminal lobes of CaM wrap around the bound peptide, interacting with the C- and N-terminal halves of the peptide, respectively. Specific CaM residues in the latch region and domain 4 were positioned in a manner consistent with their importance as determined by mutagenesis studies. The crystal structure also suggested a basis for tighter CaM binding in iNOS: because iNOS contains a greater number of hydrophobic residues within its corresponding CaM recognition sequence, it was argued that these would support more extensive van der Waals contacts with CaM and minimize unfavorable solvent exposure of hydrophobic residues in order to favor tighter association between CaM and the iNOS CaM recognition sequence.

The crystal structure of a complex between Ca^{2+} /CaM and the FMN domain of human iNOS is also available. Four different conformations were identified in the structure of the complex, which demonstrates the flexible nature of CaM and FMN domain-domain interactions. A salt bridge formed between CaM and the FMN domain is apparent in the structure and may be important for transducing the effect of CaM binding on NOS functions.

Ca^{2+} /CaM Regulation of NOS

How Ca^{2+} /CaM regulates NO synthesis and heme reduction in NOS is not entirely clear. CaM binding does not appear to change the thermodynamic driving force for electron transfer in NOS and instead may control the electron transfer primarily via structural rearrangement. CaM binding likely induces a relatively large conformational rearrangement which then enables the FMN subdomain to get close enough to the NOS oxygenase domain heme to make electron transfer between them more efficient.

Some cellular proteins that bind to NOS can regulate its response to Ca^{2+} /CaM. These include caveolins, dynamin, the bradykinin β -2 receptor, and heat shock protein-90. In addition, several different structural elements that are present in NOS regulate its interaction and response to Ca^{2+} /CaM. These include the canonical CaM-binding site in each NOS and at least four other structural elements within the reductase domain (Table 1, Figure 2).

Initially, it was imagined that the CaM interaction with each NOS isoform might depend solely on its CaM recognition sequence. However, when the CaM-binding sequences of both eNOS and nNOS were replaced with the corresponding sequence from iNOS, enzyme still required added Ca^{2+} for full CaM binding and activity. Other deletion studies have

Table 1 NOS structural elements involved in its Ca^{2+} /CaM response

<i>NOS structural element</i>	<i>Role</i>
CaM binding site	Binds CaM to NOS; is inhibitory in the absence of CaM
Autoinhibitory loop	Impacts Ca^{2+} concentration response, represses NOS activity in the absence of CaM, also required for full CaM response
C-terminal extension	Impacts Ca^{2+} concentration response, represses NOS activities in the absence of CaM, also required for full CaM response
Amino acid K842 in the autoinhibitory loop of nNOS	Impacts Ca^{2+} concentration response, helps to repress NOS activities in the absence of CaM, also stabilizes closed conformation of NOS reductase domain
R1400 in C-terminal tail of nNOS	Helps to repress NOS activities in the absence of CaM through ionic interaction with 2-phosphate group of bound NADP(H).
Amino acid 484–726 in the FMN subdomain of iNOS	Required for Ca^{2+} -independent CaM-binding to iNOS
Acidic amino acid (E762, E789, E790, D813, E816, E819) on the surface of FMN subdomain of nNOS	Helps to repress NOS activities in the absence of CaM, also required for CaM to relieve the repression
Amino acid R1229 in the FAD subdomain of nNOS	Helps to repress NOS activities in the absence of CaM, also required for CaM to fully relieve the repression
CD2 loop in reductase domain of eNOS	Impacts Ca^{2+} concentration response, represses NOS activities in the absence of CaM
Phe1395 in FNR subdomain of nNOS	Helps to repress NOS activities in absence of CaM, also required for CaM to fully relieve the repression
Phosphorylation sites in eNOS S1179	Phosphorylation impacts Ca^{2+} concentration response and increases enzyme activity
T497	Dephosphorylation increases enzyme activity
S635	Phosphorylation may impact enzyme activity
S617	Phosphorylation impacts Ca^{2+} concentration response, no change in enzyme activity

identified short regions within the iNOS and eNOS reductase domains that modulate the NOS Ca^{2+} requirement and CaM affinity in a positive or negative manner (1). Finally, there are several amino acids that can undergo phosphorylation within the NOS reductase domains and CaM-binding sites (Figure 2). Phosphorylation at these individual or combined sites in NOS alters the CaM response with regard to its Ca^{2+} concentration

requirement and may also alter the maximal level of enzyme activation that is achieved.

Autoinhibitory Loop

One regulatory element that is unique to NOS is the autoinhibitory loop insert (Figure 2). Constitutive NOSs (e.g., eNOS and nNOS) contain a 40–50-amino-acid insert in their FMN-binding module that is not shared with iNOS or with other related flavoproteins. Similar autoinhibitory loops have been reported in a number of CaM-dependent enzymes, including CaM-dependent protein kinase II, smooth muscle myosin light chain kinase, and calcineurin. Peptides based on the eNOS insert sequence inhibited NOS enzymatic activity by altering their CaM binding. For instance, deletion of the insert in eNOS or nNOS decreased their EC_{50} for Ca^{2+} , confirming that the insert was inhibitory (i.e., causes the enzyme to require a higher Ca^{2+} concentration to enable its CaM response). Deleting the autoinhibitory peptide also enables some NO synthesis in the absence of CaM and increases the intrinsic catalytic activity of CaM-bound eNOS. Thus, the insert contributes to the Ca^{2+} dependence of the constitutive NOS and also regulates the electron transfer between its FMN and heme centers.

How the autoinhibitory insert participates in Ca^{2+} /CaM regulation is still unclear. One model has the insert docking on a site in NOSs that impedes both CaM binding and the structural rearrangement that is expected to be required for enzymatic activation. Upon binding, the Ca^{2+} /CaM, a conformational change that displaces the autoinhibitory insert from its docking site would then relieve the inhibitory effect and facilitate activation of the enzyme. A two-stage model seems reasonable to explain the Ca^{2+} /CaM activation in NOSs: CaM binding is largely determined by the recognition sequence and some other interactions with the enzyme. However, activation of the enzyme is fully dependent on a movement of the autoinhibitory insert, which could only be affected by the Ca^{2+} -saturated CaM. The conformational change induced by Ca^{2+} /CaM is passed on to the autoinhibitory insert, and this in turn presumably enables the enzyme reductase and oxygenase domains to adopt conformations that lead to productive electron transfer between the FMN and heme redox centers.

C-Terminal Extension

Another regulatory element that is unique to NOS is the C-terminal extension. The protein sequences of NOS reductase domains closely resemble that of NADPH-cytochrome P450 reductase (CPR). However, all NOS isoforms have an additional 20–40 residue extension in their C terminus, forming a tail that is absent in CPR. Deletion of 33 or 42 C-terminal residues from nNOS or eNOS speeds electron transfer into the flavins, implying that the C-terminal extension is a negative regulator. Another NOS mutant with a partial deletion of the C-terminal extension ($\Delta 27$ eNOS) exhibited a lower Ca^{2+} concentration response and an increase in some of its catalytic activities. Importantly, there is an Akt-dependent phosphorylation site located in the C-terminal tail of the constitutive NOS enzymes that modulates their regulation by Ca^{2+} /CaM (Figure 2). Phosphorylation at this site relieves some of the repression attributed to the C-terminal tail in the absence of CaM. It also lowers the Ca^{2+}

Figure 2 Sequence of eNOS–CaM binding site and reductase domain. Colored rectangles indicate subdomains that make up the reductase domain. Structural elements and phosphorylation sites that impact Ca^{2+} /CaM regulation of NOS are noted in italics.

concentration that is required for CaM binding and increases the NO synthesis activity of eNOS (but not of nNOS). When the autoinhibitory loop is present (as in nNOS and eNOS), the C-terminal tail is also needed to enable full activation in response to Ca^{2+} /CaM. This indicates that it functions as a positive regulatory element under this circumstance.

Ca^{2+} /CaM regulation of NOS may involve the above two regulatory elements in the following manner. In the absence of CaM, the C-terminal extension helps to cover the NADPH-FAD and FMN subdomain interfaces, and this inhibits (but does not completely prevent) the FMN subdomain from transferring electrons to redox partners like Cyt *c* or the NOS heme. This repression by the C-terminal tail requires that the enzyme NADPH binding site be occupied. Under this condition, the autoinhibitory insert is positioned in a way that antagonizes CaM binding and prevents the FMN subdomain from interacting productively with the NOS oxygenase domain. Upon CaM binding, the autoinhibitory loop swings away and this conformational change enables interactions between the FMN subdomain and the oxygenase domain that are productive for electron transfer to the heme. Specific interactions between the C-terminal extension and the autoinhibitory insert are likely to occur within the CaM-bound NOS. Such interactions between the two regulatory elements are likely to enable full activation of electron transfer by Ca^{2+} /CaM. Thus, the autoinhibitory loop and C-terminal tail repress enzyme function in the absence of CaM, and help to positively modulate function when Ca^{2+} /CaM is bound. Other structural elements that are present in the NOS reductase domain (1) along with protein phosphorylation events also help to regulate Ca^{2+} /CaM binding and to tune its activation of enzyme catalysis.

Glossary

Adenosine triphosphate (ATP) The biochemical molecule utilized by the cells as energy source.

Apoptosis A type of cell death, characterized by specific morphological changes (i.e., chromatin condensation, DNA damage, and shrinkage of the cells) and utilized by organisms to regulate the growth and the development of tissues, organs, etc. Also called 'programmed cell death'.

Caspases Protein family responsible for degradation of specific proteins that contain recognizing sequences.

Their activation leads to signals of programmed cell death.

G protein Protein associated to specific hormone receptor of the plasma membrane and responsible for the conversion of extracellular signals into intracellular messages.

Respiratory chain A series of multisubunit proteins located in the inner mitochondrial membrane responsible for the electron and proton transfer necessary to generate the electrochemical gradient used for ATP production.

The Origins and the Fundamental Principles

Studies of Ca^{2+} transport in isolated mitochondria began in the 1960s when evidence was provided that isolated, respiring mitochondria accumulate Ca^{2+} in the presence of inorganic phosphate. Ca^{2+} uptake was inhibited by respiratory chain blockers but not by the adenosine triphosphate (ATP) synthesis inhibitor oligomycin, and, during Ca^{2+} uptake, no adenosine diphosphate (ADP) phosphorylation took place. In the presence of ATP, no respiratory chain was necessary. Thus, the process of Ca^{2+} uptake was regarded as an alternative pathway to ADP phosphorylation for the use of the respiratory chain energy. In this scenario mitochondria were thought as large stores of Ca^{2+} , which could be accumulated together with inorganic phosphate and precipitate in the matrix, leaving its free Ca^{2+} concentration virtually unchanged.

The general picture became clearer when the chemiosmotic theory solved the mechanism allowing mitochondria to store the energy obtained from metabolite breakdown and couple it to ATP synthesis. Indeed, the concept that the respiratory chain, by pumping protons across the ion-impermeable inner membrane, establishes a gradient ($\Delta\mu_{\text{H}^+}$), composed of an electrical potential ($\Delta\psi$) and a concentration ratio (ΔpH), according to the Nernst equation, $\Delta\mu_{\text{H}^+} = zF\Delta\psi + RT \ln[\text{H}^+]_{\text{i}}/[\text{H}^+]_{\text{o}}$, has major implications for Ca^{2+} transport and distribution. In actively respiring mitochondria, considering the buffering capacity mostly provided by weak acids, the gradient is supposed to be maintained mostly in the form of electrical gradient across the inner membrane (~ 180 mV). This implies a strong thermodynamic force in favor of the accumulation of cations (in the case of a divalent cation, such as Ca^{2+} , thermodynamic equilibrium is attained when in the matrix the concentration is approximately 10^6 higher than in the intermembrane space). Based on these simple considerations, large attention was drawn in the 1960s and 1970s on the capacity of mitochondria to accumulate Ca^{2+} , and on the biochemical and thermodynamic properties of this transport. Through the contribution of numerous laboratories and a large body of experimental work carried out in isolated, respiring mitochondria, these organelles were shown to possess separate

accumulation and release pathways for the cation, with defined characteristics. Accumulation was shown to depend on the activity of an electrogenic uniporter that transports Ca^{2+} down the electrical gradient established by the respiratory chain. Inhibition of the respiratory chain or collapse of the electrical gradient (e.g., by the use of a protonophore) abolishes the capacity of mitochondria to accumulate Ca^{2+} . Ca^{2+} uptake is also directly inhibited by the compound Ruthenium Red (or its recently identified subcomponent Ru360) or lanthanides. Unfortunately, none of the inhibitors is highly specific; thus, no selective tool has aided the purification of the transporter. Through the years, many attempts have been made to identify the uniporter and some putative candidates have been proposed but, only very recently, this key transporter has been truly identified. As to the release pathways, two sets of exchangers have been shown to extrude Ca^{2+} from mitochondria: a $\text{Na}^+/\text{Ca}^{2+}$ exchanger, mostly expressed in excitable cells (muscle and brain), and a $\text{H}^+/\text{Ca}^{2+}$ exchanger that represents the prevailing route in most other tissues. Both exchangers (albeit with different K_{d}) are inhibited by verapamil, diltiazem, and other Ca^{2+} channel blockers. Very recent evidence indicates that $\text{Na}^+/\text{Ca}^{2+}\text{-Li}^+$ exchanger (NCLX), the single mammalian member of the phylogenetically ancestral Ca^{2+} /cation exchanger family, initially characterized as a novel plasma membrane $\text{Na}^+/\text{Ca}^{2+}$ exchanger that catalyzes Na^+ - or Li^+ -dependent Ca^{2+} transport, is the long elusive mitochondrial $\text{Na}^+/\text{Ca}^{2+}$ exchanger.

More recently, much attention has been drawn to the potential role of a large-conductance channel, commonly referred to the permeability transition pore (PTP). It is supposed to be a multiprotein complex (the putatively essential components being the voltage-dependent anion channel (VDAC) of the outer membrane, the adenine nucleotide transporter of the inner membrane and cyclophilin D) activated by various pathophysiological conditions (e.g., Ca^{2+} increases in the mitochondrial matrix and oxidation of critical cysteines). As to the (patho)physiological role, it is most likely involved in the swelling and fragmentation of the mitochondrial network that underlies the release of caspase cofactors from mitochondria. Its molecular identity is still unknown.

The Middle Ages

In the 1980s, mitochondrial participation in intracellular Ca^{2+} homeostasis rapidly lost support, as the focus in Ca^{2+} signaling was largely diverted to the endoplasmic reticulum (ER). In these years, the chain of events that couples the stimulation of plasma membrane receptors to the induction of a rise in cytoplasmic Ca^{2+} concentration was clarified, and it became clear that the ER, and not mitochondria, were the main site of action. Indeed, stimulation of receptors coupled, through a G_q protein, to the activation of phospholipase C induces the hydrolysis of the plasma membrane phosphatidylinositol-4,5-bisphosphate into diacylglycerol and inositol-1,4,5-trisphosphate (IP3). IP3 diffuses into the cytosol and interacts with Ca^{2+} -permeant channels of the ER membrane, causing their opening and the release of Ca^{2+} into the cytoplasm. The ER (and its specialized version of muscle cells, the sarcoplasmic reticulum) was shown to be endowed with a molecular repertoire allowing it to act as a highly reactive intracellular Ca^{2+} store: pumps (that accumulate Ca^{2+} at the expense of ATP hydrolysis and maintain a standing gradient between the lumen and the cytosol), low affinity Ca^{2+} -binding proteins (that increase the net amount of cation that can be accumulated, but promptly make it available when the concentration in the lumen decreases), and channels (opening, with different mechanisms, after stimulation of plasma membrane receptors).

What was left for mitochondria? In principle, given the large thermodynamic force for Ca^{2+} accumulation, they could take up most of the Ca^{2+} released by the ER. In the same years, however, the availability of powerful and versatile Ca^{2+} indicators, the intracellularly trappable fluorescent dyes (e.g., quin2 and fura-2), allowed us to carefully estimate the cytosolic Ca^{2+} concentration ($[\text{Ca}^{2+}]_c$) of living cells and further reduced the possible roles of mitochondria. Indeed, these indicators showed that both at rest (0.1 μM) and upon stimulation (1–3 μM), the $[\text{Ca}^{2+}]_c$ is well below the affinity of the mitochondrial uniporter, and thus very little Ca^{2+} is supposed to be accumulated in mitochondria during the brief pulse of a physiological stimulation. Thus, the general consensus incorporating this series of information was that mitochondria acted as a low-affinity sink that could accumulate large Ca^{2+} loads, but only if the cell was exposed to challenges (most likely pathological events) that induced sustained, large $[\text{Ca}^{2+}]_c$ increases. In other words, mitochondria were mostly intended as salvage mechanisms against deleterious Ca^{2+} overloads.

The Renaissance

In this situation, the only opportunity for mitochondria to obtain credit in the Ca^{2+} field was to directly demonstrate in intact, living cells changes in mitochondrial $[\text{Ca}^{2+}]$ occurring in physiological conditions. This became possible in the early 1990s, when novel experimental tools allowed us to specifically measure the Ca^{2+} concentration in the mitochondrial matrix ($[\text{Ca}^{2+}]_m$): positively charged fluorescent indicators, that are largely accumulated in the mitochondria and molecularly engineered chimeras of the Ca^{2+} -sensitive photoprotein

aequorin, that include mitochondrial targeting sequences and are thus exclusively localized in the mitochondrial matrix. Using these probes, it was possible to demonstrate that, in a variety of cell systems (ranging from epithelial cells to skeletal and cardiac myocytes, from hepatocytes to neurons), the $[\text{Ca}^{2+}]_c$ rises evoked by physiological stimulations are always paralleled by rapid $[\text{Ca}^{2+}]_m$ increases that reach values well above those of the bulk cytosol (up to $\sim 500 \mu\text{M}$ in chromaffin cells). The obvious discrepancy between this prompt response and the low affinity of the Ca^{2+} uniporter was reconciled by the demonstration that mitochondria are exposed to microdomains of high $[\text{Ca}^{2+}]$ that largely exceed the values reported in the bulk cytosol and meet the low affinity of the uniporter. This is achieved through a close interaction between the mitochondria and the ER, the intracellular Ca^{2+} store, which could be directly demonstrated using targeted chimeras of a fluorescent recombinant protein (green fluorescent protein (GFP)) and a high-resolution imaging system. A consequence of this morphological arrangement is the capacity of mitochondria to sense the microenvironment at the mouth of the IP3-sensitive channel (and/or the plasma membrane Ca^{2+} channels), and thus the high $[\text{Ca}^{2+}]_c$ generated by their opening upon cell stimulation (Figure 1).

One (or Many) Roles?

What is the functional significance of the re-evaluated mitochondrial Ca^{2+} transport? An obvious answer again stems from biochemical work by Denton, McCormack, and Hansford in the 1960s, who could demonstrate that three key metabolic enzymes (the pyruvate, α -ketoglutarate, and isocitrate dehydrogenases) are activated by Ca^{2+} , by different mechanisms: in the case of pyruvate dehydrogenase through a Ca^{2+} -dependent dephosphorylation step, in the latter two cases through the direct binding of Ca^{2+} to the enzyme complex. Thus, the extension of a Ca^{2+} signal originated in the cytoplasm to the mitochondria would serve the purpose of transmitting an activatory signal to the energy powerhouse of the cell; thus, in conjunction to the triggering of energy-consuming processes in the cytosol (contraction, secretion, etc.) mitochondrial dehydrogenases are stimulated, thus adapting aerobic metabolism to the increased needs of an active cell. Using the luciferase-based probe for ATP, it was possible to demonstrate that a rise in mitochondrial ATP levels parallels the $[\text{Ca}^{2+}]_m$ increase evoked by cell stimulation and strictly depends on the $[\text{Ca}^{2+}]_m$ rise; if the latter is prevented by the use of Ca^{2+} chelators, such as 1,2-bis(O-aminophenoxy)ethane-*N,N,N',N'*-tetraacetic acid (BAPTA), also the [ATP] rise does not occur.

However, recent work by different groups has clarified that the role of mitochondrial Ca^{2+} uptake is not limited to the control of organelle function, but has a direct impact on the Ca^{2+} signals evoked by agonist stimulation in the cytosol. Two different mechanisms concur in this effect. The first occurs in the microdomains where mitochondria and ER get in close contact. Here, the efficiency of mitochondrial Ca^{2+} accumulation accounts for the rapid clearing of the high $[\text{Ca}^{2+}]$ at the mouth of the release channel of the ER and thus reduces the (positive or negative) feedback effect of the cation on the channel itself. Such a mechanism has been shown in a

Figure 1 Mitochondrial Ca^{2+} transport. Cell stimulation induces the opening of plasma membrane Ca^{2+} channels and ER Ca^{2+} channels (IP3R and RyR), which, in turn, generates hot spots of Ca^{2+} concentration. Mitochondria located in the Ca^{2+} channels proximity could rapidly take up Ca^{2+} since their low affinity uniporter could experience high local Ca^{2+} concentrations. The three traces represent measurements of $[\text{Ca}^{2+}]$ in the three cellular compartments shown, performed with suitably targeted aequorin.

variety of experimental systems ranging from *Xenopus* oocytes (in which the diffusion properties of Ca^{2+} waves correlate with the energization state of mitochondria) to mammalian cells such as hepatocytes and glial cells, where it was demonstrated that the kinetics of Ca^{2+} release from the ER, and thus the spatio-temporal properties of the $[\text{Ca}^{2+}]_c$ rise are influenced by the process of mitochondrial Ca^{2+} uptake.

The second mechanism by which mitochondrial Ca^{2+} uptake affects cytosolic Ca^{2+} signals has been demonstrated in pancreatic acinar cells that are endowed with a defined polarized morphology and the occurrence of cellular Ca^{2+} signals with different cellular locations and physiological consequences. Namely, at lower doses of agonist (e.g., colecystokinin), the $[\text{Ca}^{2+}]_c$ rise is restricted to the apical pole and causes granule secretion; at higher doses, the $[\text{Ca}^{2+}]_c$ rise extends to the basal pole (where the nucleus is located), thus causing activation of gene expression and long-term alterations of cell function. The restriction mechanism was shown to be dependent on Ca^{2+} uptake by mitochondria clustered below the apical region that act as a firewall preventing the spreading of the $[\text{Ca}^{2+}]_c$ rise. When the mitochondrial belt is overwhelmed (e.g., upon intense stimulation, or when the Ca^{2+} uptake capacity of mitochondria is experimentally impaired), then the Ca^{2+} signal can freely diffuse to the rest of the cell.

Finally, in the past years a more dangerous role for mitochondrial Ca^{2+} uptake has emerged. Work from various labs has revealed that the alteration of the Ca^{2+} signal reaching the

mitochondria and/or the combined action of apoptotic agents or pathological conditions (e.g., oxidative stress) can induce a profound alteration of organelle structure and function. As a consequence, proteins normally retained in the organelle (such as an important component of the respiratory chain, cytochrome *c*, as well as newly discovered proteins, such as apoptosis-inducing factor and Smac/Diablo) are released into the cytoplasm, where they activate effector caspases and drive cells to apoptotic cell death. Different effects have been described: in hepatocytes, upon treatment with suboptimal doses of the lipid mediator of apoptosis ceramide, the repetitive spiking of cytoplasmic Ca^{2+} concentration ($[\text{Ca}^{2+}]_c$) rather than triggering the activation of matrix dehydrogenases (and thus the stimulation of aerobic metabolism) causes the opening of the PTP, the swelling of mitochondria, and the release of cytochrome *c*. Thus, a mechanism of coincidence detection of physiological agonists and apoptotic stimuli allows the specific induction of the apoptotic program (the mitochondria acting as the site where this differential decoding is operated). In addition, apoptotic stimuli can induce the impairment of the Ca^{2+} -clearing mechanism of the cell (the plasma membrane Ca^{2+} -ATPase), thus potentiating Ca^{2+} loading. In this scenario, it can be easily understood how the partial depletion of Ca^{2+} from the ER, induced by the oncogene Bcl-2, has a protective effect toward some apoptotic stimuli (those involving mitochondria in the signaling pathway). Both in neurons and in hepatic cells, it was observed that apoptotic signals cause mitochondrial Ca^{2+} overload and thus the apoptotic

Physiological conditions

Apoptotic agents and/or alteration of the Ca²⁺ signal

morphological and functional alterations. A general scheme of the physiological role of mitochondrial Ca²⁺ signaling, and the potential alterations occurring in pathological conditions (modifying the final outcome) is summarized in [Figure 2](#).

The Molecular Machinery

The Outer Membrane Channels

Mitochondrial Ca²⁺ effectors are mostly located within the matrix, and Ca²⁺ elevation in the latter compartment requires the crossing of the outer membrane (OMM), known to be highly permeable to ions and small solutes, and the ion-impermeable inner membrane. While great interest was placed

on the identification of the transporters of the inner membrane, the elucidation of the permeation properties and the correlation with organelle structure and function, recent data have however also pointed to an important role of the fine-tuning of the outer membrane permeability. Indeed, the repertoire of VDAC channels clustered at the ER/mitochondrial contact sites appears limiting for the Ca²⁺ uptake capacity of the organelle. Overexpression of VDAC channels causes a significant increase in the peak [Ca²⁺] values reached upon cell stimulation and, in high-speed single cell imaging experiments, reduces the delay between the cytosolic and mitochondrial uptake, thereby indicating that VDAC channels play a key role in the rapid transfer of the high Ca²⁺ microdomain from the surface of mitochondria to the intermembrane space to which the low-affinity mitochondrial

Ca^{2+} uniporter (MCU) is exposed. VDAC shuttles from an open and closed state (with reference to metabolite transport) and the closed state shows a higher permeability to Ca^{2+} . Interestingly, Ca^{2+} itself appears to control the conductance of VDAC, thus suggesting that the OMM barrier is dynamically reduced, and mitochondrial Ca^{2+} uptake facilitated, during the Ca^{2+} signal.

The Inner Membrane Transporters

The ion-impermeable inner membrane (IMM) is obviously the key site of mitochondrial Ca^{2+} transport, and the identification of the IMM Ca^{2+} transporters has been a long-pursued aim. In particular, major effort has been placed by numerous labs in giving a molecular identity to the MCU, the electrophoretic system that has the properties of a highly selective ion channel and allows Ca^{2+} to be accumulated down the electrical gradient established by the respiratory chain. The effort proved for a long time ineffective, because simpler model systems, such as yeast, do not have MCU activity, no specific inhibitor could be employed for protein purification, and homology search with known Ca^{2+} channels did not yield convincing candidates. Thus, although the general properties of mitochondrial Ca^{2+} handling have been known for nearly half a century, no mitochondrial Ca^{2+} transporters have been identified and validated for a long time.

In the past year, however, the molecular search of Ca^{2+} transporters has benefited from powerful genomic or proteomic approaches, yielding interesting candidates that require careful consideration. Clapham and co-workers carried out an impressive genome-wide RNA interference screening with a mitochondrially targeted pericam in *Drosophila* S2 cells, obtaining an interesting list of proteins affecting mitochondrial Ca^{2+} accumulation. They focused their attention on LETM1, previously reported to be a mitochondrial K^+/H^+ exchanger, and showed that its silencing depressed mitochondrial Ca^{2+} accumulation triggered by cell stimulation, while leaving the $\Delta\psi_m$ unaffected. Based on their data, the authors propose that LETM1 is a $\text{Na}^+/\text{Ca}^{2+}$ antiporter mediating Ca^{2+} accumulation into the matrix. These conclusions, however, remain controversial, as some key data appear in contrast with established evidence: (1) antiporter inhibition by CGP37157 augments, and not reduces, Ca^{2+} accumulation; (2) in contrast to the MCU, antiporters are known to be insensitive to Ruthenium Red; and (3) the accepted stoichiometry of the exchanger is $1\text{Ca}^{2+}/2\text{H}^+$ (or possibly $1\text{Ca}^{2+}/3\text{H}^+$), thus driving Ca^{2+} efflux, rather than influx, in energized mitochondria. Further work will allow us to confirm, or exclude, the direct role of LETM1 in mitochondria Ca^{2+} handling.

Another interesting approach has been pursued by Mootha and co-workers, who made the precious effort of generating a mitochondrial genome (MitoCarta), that is, a compendium of nuclear genes coding for proteins with mitochondrial localization validated by proteomic analysis and GFP tagging. By screening this list for expected properties of MCU (e.g., ubiquitous expression and absence in *Saccharomyces cerevisiae*), they initially identified a protein, which they named 'mitochondrial calcium uptake 1' (MICU1). MICU1 is a protein associated with the IMM, including two EF-hand Ca^{2+} -binding sites and a single putative transmembrane stretch. Its silencing abolishes mitochondrial Ca^{2+} uptake in intact and permeabilized cells, without

interfering with mitochondrial respiration or membrane potential. Moreover, MICU1 is required for the metabolic coupling between cytosolic Ca^{2+} transients and activation of matrix dehydrogenases. While it is unlikely that MICU1 is the bona fide channel, the data strongly argued for a key regulatory role and suggested that mitochondrial Ca^{2+} uptake depends on a macromolecular complex. Few months later, the judicious analysis of Mitocarta by two independent groups allowed to identify an integral inner membrane protein satisfying the criteria for being the MCU. The protein, denominated MCU, is ubiquitously expressed in mammals and has two predicted transmembrane regions connected through a loop enriched in acidic residues. Its small interfering RNA silencing inhibited mitochondrial Ca^{2+} accumulation in intact cells, whereas its overexpression dramatically increased it. The channel activity of purified MCU reconstituted in a planar lipid bilayer revealed the properties previously reported for the uniporter, thus conclusively demonstrating that MCU *per se* represents the bona fide calcium channel of the inner mitochondrial membrane. In addition, mutation of the putative pore region not only inhibited channel activity, but the mutant channel also acted as dominant negative in intact cells, thus suggesting that ion permeation requires the presence of multiple subunits in an oligomer.

Finally, molecular information has recently been obtained also on the efflux pathways, that is, the mitochondrial exchangers (the $\text{Na}^+/\text{Ca}^{2+}$ exchanger, mNCX, and $\text{H}^+/\text{Ca}^{2+}$ exchanger, mHCX) that re-extrude the cation out of the matrix, preventing the attainment of thermodynamic equilibrium and allowing the return of $[\text{Ca}^{2+}]_m$ to basal values after cell stimulation. Sekler and coworkers identified NCLX as the only mammalian member of a phylogenetically ancient branch of the $\text{Na}^+/\text{Ca}^{2+}$ exchanger superfamily, and proved it to be enriched in mitochondrial fractions and transport both Na^+ and Li^+ , as expected of the mNCX. Overexpression and silencing enhanced and reduced mitochondrial Ca^{2+} efflux in intact cells, and Ca^{2+} transport was inhibited by CGP37157. Overall, the data are fully consistent with the notion that the identified protein is the bona fide mitochondrial $\text{Na}^+/\text{Ca}^{2+}$ exchanger, opening this branch of the Ca^{2+} transport machinery to detailed molecular investigation.

Conclusions

Work in the past years has greatly re-evaluated mitochondrial Ca^{2+} homeostasis not only as a key event for the maintenance of ion balance within the organelle (avoiding deleterious short-circuiting of the chemiosmotic machinery), but also as a control mechanism for physiological and pathological processes occurring in mitochondria, or activated by mitochondrial factors. Thus, both in basic and applied research there is an expanding interest on this topic, that now benefits of the very recent identification of the key molecules involved (the NCX, MICU1, a uniporter regulator and MCU, the uniporter itself). The molecular machinery is thus essentially solved: now exciting times will come, in which proteomic analyses, transgenic models, and pharmacological studies will allow to unravel the function of mitochondrial Ca^{2+} homeostasis in normal and pathological conditions.

Glossary

C2 domain Common Ca^{2+} -binding structure composed of eight antiparallel β -strand structures (β sandwich structure).

Calpain homepage Calpain-related information (sequence, commercially available reagents) are summarized on the calpain homepages listed in the section Relevant Websites.

Cysteine protease A peptide bond hydrolyzing enzyme whose active site is composed of a catalytically active cysteine residue.

EF-hand motif Common Ca^{2+} -binding motif composed of two α -helices (E- and F-helices) and a Ca^{2+} -binding loop in between them.

Limb-girdle muscular dystrophy (LGMD) Heterogeneous sets of muscular dystrophies mainly affecting proximal muscles. Thus far, close to 20 responsible genes have been identified. Among them, LGMD type 2A (LGMD2A) is caused by mutations in muscle-specific calpain, p94/calpain 3, and also called ‘calpainopathy’.

Lissencephaly Lissencephaly literally means smooth brain. A rare brain formation disorder caused by defective neuronal migration during the 12th to 24th weeks of gestation, resulting in a lack of development of brain folds and grooves. Children with lissencephaly are severely neurologically impaired and often die within several months of birth.

Musculardystrophy Progressive deterioration of muscle tissue and resultant weakness caused by a defect of the number of muscle genes such as dystrophin, sarcoglycan, merosin, laminin, and calpain. The information on pathogenic mutations of muscular dystrophies is available in the Leiden Muscular Dystrophy pages.

Noninsulin-dependent diabetes mellitus (NIDDM) Also called diabetes mellitus type 2, type 2 diabetes, or adult-onset diabetes. A disorder that is characterized by high blood glucose in the context of insulin resistance and relative insulin deficiency.

Introduction

Calpains denote a unique branch of cysteine proteases, which have amino acid sequences significantly similar to that of the protease domain of human μ -calpain, the major Ca^{2+} -dependent protease, and constitute a superfamily (Clan CA, family C02, EC 3.4.22.17). Among them, most studied calpains are μ -calpain and m-calpain, which are called ‘conventional calpains’. Mammalian conventional calpains are mainly localized in the cytosol, show ubiquitous expression, and display limited proteolytic activity at neutral pH. The mode of its action is processing, rather than digesting; calpain proteolyzes substrates at one or very limited number of sites to transform and modulate their structures and activities. Thus, calpain is viewed as a representative intracellular modulator protease that governs various cellular functions such as signal transduction and cell morphogenesis.

Calpain belongs to the papain superfamily that is composed of the three distinct kingdoms, that is, calpain, papain, and bleomycin-hydrolase subfamilies. The human genome has 15 genes that encode a calpain-like protease domain (see [Figure 1](#) and [Table 1](#)). These generate diverse types of calpain homologs possessing combinations of several functional domains such as a Ca^{2+} -binding domain (C2-type and penta-EF-hand (PEF)-type) and a Zn-finger domain. Furthermore, the progress in genome projects revealed that calpain homologs exist in various living organisms including insect, nematode, trypanosome, plant, fungus, yeast, and even some bacteria, thus constituting a superfamily, even in an evolutionary aspect, possessing versatile functions ([Figure 1](#)). The importance of the physiological roles

of calpains is reflected by the fact that particular defects in calpain functionality cause a variety of deficiencies in many different organisms. These include muscular dystrophies, lissencephaly and tumorigenesis in humans, embryonic lethality in mice, impaired neurogenesis in flies, lack of definitive sex determination in nematodes, defects in aleurone cell development in maize, and alkaline/osmotic stress susceptibility in fungi and yeasts. In the following sections, with several disease-related topics of calpains, divergent physiological roles of calpains are described mainly from the viewpoint of structure–function relationship.

History and Nomenclature

An enzyme corresponding to calpain was first described in 1964 by Gordon Guroff in the *Journal of Biological Chemistry*. After several reidentifications, calpain, which was called ‘calcium-activated neutral protease (CANP)’ at that time, was finally molecularly cloned in 1984 by Koichi Suzuki’s group. The complementary DNA (cDNA) sequence for the catalytic subunit of calpain revealed that calpain is a chimeric molecule consisting of a cysteine protease and a calmodulin-like Ca^{2+} -binding module. Both names, calpain and CANP, were unified as calpain in 1991 in the annual meeting of the International Committee on Proteolysis held in Munich. In the two decades following this event, hundreds of calpain-related molecules, including its endogenous specific inhibitor protein, calpastatin, have been identified through the use of cDNA cloning and genome/expressed sequence tag (EST) projects ([Figures 1 and 2](#)).

Figure 1 Schematic structures of calpain superfamily members. Calpain homologs have been identified in vertebrates, insects, nematodes, schistosomes, trypanosomes, plants, fungi, yeasts, some bacteria, etc. Symbols used are: I, the N-terminal domain with little homology; IIa and IIb, the protease sub-domains containing the active sites Cys and His, respectively; III, the C2-like Ca^{2+} -binding domain; III' and III'', domains moderately and very weakly similar to the domain III, respectively; IV and VI, the 5-EF-hand Ca^{2+} -binding domain; V, Gly-rich hydrophobic domain; NS, IS1, and IS2, p94-specific sequences; T, TRA-3 subfamily-specific C2 domain; MIT, Microtubule-interacting and trafficking domain; Zn, Zn-finger motif containing domain; SOH, SOL subfamily homology domain; DIS, CALPA-specific insertion sequence; TM, transmembrane domain; CSTN, the domain weakly similar to calpastatin.

Two major ubiquitous calpains are found in mammals, μ - and m-calpains. As most of the calpain studies have been actually the studies about μ - and m-calpains, they are referred to as the conventional calpains. As the names suggest, μ -calpain and m-calpain are activated by μM and mM levels of Ca^{2+} *in vitro*, respectively. They are both hetero-dimers and consist of a common calpain small regulatory subunit (CAPNS1, also called '30 K'; *c.* 28 kDa) and large distinct μ - and m-calpain catalytic subunit (μCL and mCL , respectively; *c.* 80 kDa), which have $\sim 60\%$ amino acid identity. Fifteen human calpain homologs have been numbered according to the gene name as shown in Table 1 and Figure 1. As an example, μCL is now called 'calpain 1' or CAPN1, that is, μ -calpain is a hetero-dimer consisting of a CAPNS1 regulatory subunit and calpain 1

catalytic subunit. To avoid unnecessary confusions, however, the original name and the gene product name are adopted in this article, for example, μCL /CAPN1, mCL /CAPN2, p94/CAPN3, 30 K/CAPNS1, hTRA-3/CAPN5, etc.

Structure and Function of Conventional Calpains

In general, substrates for calpains are limited and specific. Most short oligopeptides investigated are poor substrates for calpains. Although casein is not an *in vivo* substrate of calpain, it is a very good *in vitro* substrate and is used to assay calpain activity. Although the complete rules governing substrate specificity remain unclear, some preferences on cleavage site

^a "+" indicates that it was experimentally shown to have protease activity, and "—" means that it does not have active site cysteine, asparagine, and/or histidine residues.

^b "+" or "—" indicates that it has or does not have a corresponding domain, respectively, and "+/-" indicates that it has less than five EF-hand motifs.

Human disease and results of knock-out mice were taken together.

^c n.d., not yet determined/done; n.s., no significant phenotype; CANP, Ca^{2+} -activated neutral protease; nCL, novel calpain large subunit; LGMD2A, limb-girdle muscular dystrophy type 2A; TRA-3, transform genotypic hermaphrodites; PalB, phosphatase mutants: loss in activity at alkaline pH but normal or increased activity at acidic pH; PalBH, PalB homolog; SNP, single nucleotide polymorphism; NIDDM, non-insulin-dependent diabetes mellitus; SOL, small optic lobes; SOLH, SOL homolog.

Figure 2 Schematic structures of human calpains. (a) Schematic structures of representative products of human genes that encode calpain homologs. Blue letters indicate that these calpains are expressed tissue-specifically, whereas the others in black letters are ubiquitously expressed (see also Table 1). (b) Classification of mammalian calpains by domain structures. Symbols used are: IQ, a region interactive with calmodulin; L and XL, N-terminal and extended N-terminal regions of calpastatin; MIT, a domain interactive with microtubule; see Figure 1 for other symbols.

sequences have been reported. On the other hand, calpain is thought to also recognize a large scope of three-dimensional (3D) substrate structures. For example, protein kinases, phosphatases, phospholipases, cytoskeletal proteins, membrane proteins, cytokines, transcription factors, lens proteins, and calmodulin-binding proteins are just some of the proteins suggested to be *in vivo* substrates. There has been no report suggesting differences in substrate specificity between μ - and m-calpains.

Calpain has a very specific proteinaceous inhibitor *in vivo* called calpastatin. Calpastatin has four repeats of an inhibitor unit, each of which inhibits one molecule of calpain (Figure 2 (a)). Both μ - and m-calpains possess similar susceptibility to calpastatin. Among other calpain homologs, novel calpain large subunit (nCL)-2/CAPN8 and nCL-4/CAPN9, but not p94/CAPN3, are also inhibited by calpastatin. The μ - and m-calpains are ubiquitously expressed in vertebrate cells. Thus, their function is thought to be fundamental and essential. Many functions including the regulation of signal transduction systems, cell motility, and apoptosis have been suggested, although their precise physiological roles are still elusive. *Capn1* knockout mice showed almost no phenotype, while *Capn2* and *Capns1* knockout mice resulted in embryonic lethality, indicating the indispensable roles of conventional calpains and, at the same time, differentiating between μ - and m-calpain functionality and/or amounts expressed.

As shown in Figure 2(a), the catalytic and regulatory subunits of conventional calpains can be divided into four and two domains, respectively. The N-terminus of domain I of the large subunit is autolyzed upon the initial activation by Ca^{2+} . This results in a lower requirement for Ca^{2+} , reveal of different substrate specificity, and the dissociation of both subunits. Therefore, autolysis is one of the important regulation mechanisms of calpain activity and specificity.

3D structural studies revealed that the protease domain (domain II) in the absence of Ca^{2+} is divided into two sub-domains – domains IIa and IIb (also called domains I and II), which are folded into one domain upon Ca^{2+} binding. This domain is highly conserved among calpain family members, suggesting the functional importance of this domain (Figure 1). Rather surprisingly, the protease domain without other domains of μ - and m-calpains showed Ca^{2+} -dependent protease activity. This was explained once the 3D structural studies of the protease domain in the presence of Ca^{2+} showed that Ca^{2+} bound to domains IIa and IIb. Thus, the whole calpain molecule mediates Ca^{2+} dependency because all of the domains IIa, IIb, III, IV, and VI bind at least one Ca^{2+} with varying affinities. The 3D structure of active (Ca^{2+} -bound form of) calpain in complex with calpastatin peptide is shown in Figure 3.

The 3D structure of domain III consists of eight antiparallel β -strands (β -sandwich structure), a structure very similar to tumor necrosis factor (TNF)- α and the C2-domains found in various Ca^{2+} -regulated proteins such as protein kinase C (PKCs) and synaptotagmins. Although the primary structures of domain III are highly conserved in calpain homologs, they have no similarity to any other proteins including TNF- α and C2-domains. This C2-like domain actually binds Ca^{2+} and may play an important role in the Ca^{2+} -dependent membrane translocation of calpains.

Domain IV is very similar to domain VI of the regulatory subunit and each contains five EF-hand motifs. Thus, these domains are referred to as PEF domains. *In vitro* experiments together with 3D structural studies showed that not all EF-hands bind Ca^{2+} . The fifth EF-hand motif is involved in the dimerization of the catalytic and regulatory subunits.

Domain V of the calpain regulatory subunit contains clusters of glycine residues making it hydrophobic. This domain is thought to interact with membrane and/or membrane proteins

Figure 3 Schematic 3D structure of active rat m-calpain in complex with calpastatin peptide. Ribbon-type schematic 3D figures are drawn by FlatLux MolFeat Ver.4.5 using PDB data, 3DF0. Domain III and two PEF domains (domains IV and VI) are indicated by green and blue, respectively. The protease domain (domain II, i.e., sub-domains IIa+IIb) is given in pink and red color. Active site residues, Cys105, His262, and Asn286 (NP_058812), in the protease domain are indicated by ball-stick drawing and a white circle. Blue balls (visible in domains IIa, IIb, IV, and VI) represent Ca^{2+} . Calpastatin reactive site residues bound to domains IIa, IIb, and III of m-calpain are shown by ball-stick drawing. Dotted lines indicate invisible calpastatin polypeptide due to strong thermal vibration, which indicates the state unbound to m-calpain.

through hydrophobic interactions. Most of this domain is autolyzed during activation, indicating no involvement of this region in protease activity. In humans, the *CAPNS2* gene encodes a regulatory subunit homolog, whose physiological roles remain unclear.

Calpain Superfamily and Its Members

Classifications

As for calpain homologs other than conventional calpains, domains other than the protease domain are not necessarily conserved among homologs (Figures 1 and 2). Amino acid sequence identities of the protease domains vary, depending on the molecules, from less than 30% to more than 75%. Several kinds of domains, putatively originated from independent genes, exist in both N- and C-terminal sides of the protease domain. These include C2 and C2-like domains, a PEF domain, a transmembrane domain, Zn-finger domain, as well as conserved domains with unknown functions (e.g., SOL homology domain (SOH)). These features, together with the organization of mammalian calpain genes, strongly suggest that calpain molecules are the result of the combination of the gene for the ancestral calpain-type cysteine protease with genes encoding other functions.

Mammalian calpain homologs can be divided into two categories from the structural viewpoint. The first group consists of molecules having domains II, III, and IV (Figure 2). In other words, these group members have a typical structure highly similar to conventional calpain catalytic subunits. Beside mammalian μ CL/CAPN1 and mCL/CAPN2, typical calpains include p94/CAPN3, nCL-2/CAPN8, nCL-4/CAPN9, CAPN11, 12, 13, and 14. Chicken and *Xenopus laevis* are reported to additionally have μ /mCL, which may correspond to CAPN11. In invertebrates, only five typical calpains have been identified thus far. Three are found in *Drosophila melanogaster* as Dm-calpain/CALPA, CALPB, and CALPC. *Schistosoma mansoni* and *Schistosoma japonicum* also have at least one typical calpain (Sm-calpain and Sj-calpain). No typical calpain homologs have been found in *Caenorhabditis elegans*, plants, fungi, trypanosomes, and *Saccharomyces cerevisiae*.

The second group (atypical calpains) contains various molecules that have the protease domain but do not have overall similarity as to domains III and IV with extra domain(s). These atypical calpains are thought to have somewhat different mode of action compared with those of typical calpains. Atypical calpains include the small optic lobe (SOL) and PalB subfamilies, and several alternative splicing products of, for example, *Capn8* (nCL-2') and *CalpA*, and others. Although the structure is called atypical, PalB subfamily members are conserved in animals, fungi, and yeast, and SOL subfamily members are found in animals and green algae, but typical calpains only exist in vertebrates and *Drosophila*.

In addition to the structural features, independent classification of mammalian calpains is possible according to their tissue/organ distribution. μ CL/CAPN1, mCL/CAPN2, PalB homolog (PalBH)/CAPN7, CAPN10, CAPN13, and SOL homolog (SOLH)/CAPN15 are ubiquitously expressed, whereas p94/CAPN3, nCL-2/CAPN8, nCL-4/CAPN9, hTRA-3/CAPN5, CAPN6, 10, 11, and 12 are predominantly expressed in specific

organs (Table 1). Ubiquitous calpains play fundamental roles for all cells, whereas tissue-specific calpains are involved in functions evolved specifically in tissues they express. Therefore, defects in ubiquitous calpains often cause lethality like CAPN2, while those in tissue-specific calpains are responsible for tissue-specific diseases such as muscular dystrophy. In addition, under various disease conditions such as muscular dystrophies, cardiomyopathies, ischemic disorders, and lissencephaly, conventional calpains have trends to be over-activated probably due to the increase of intracellular Ca^{2+} concentration caused by diseases, which often aggravate the diseases. Thus, inhibitors for conventional calpains are used to prevent progression of such diseases.

Structure and Functions of Calpain Superfamily Members

Skeletal muscle-specific calpain, p94/CAPN3

p94/CAPN3, the first tissue-specific calpain found in 1989, is c. 60% identical to the large subunits of μ - and m-calpains and has a conserved domain structure (Figure 1). However, p94/CAPN3 contains three p94-specific regions, NS, IS1, and IS2, which are closely related to unique features of p94/CAPN3.

Messenger RNA (mRNA) for p94/CAPN3 is expressed predominantly in skeletal muscle and the amount expressed is approximately 10 times larger than those of conventional calpains. p94/CAPN3 possesses several unique properties. For example, p94/CAPN3 protein undergoes extremely rapid autolysis (half-life *in vitro* is less than 10 min) starting with a cut in NS and IS1, and this autolysis is obviated by deletion of IS1 or IS2. Specific inhibitors of μ - and m-calpains such as calpastatin, E-64, and leupeptin have little effect on autolysis. Furthermore, p94/CAPN3 possesses a nuclear localization signal-like sequence in IS2 and is localized in the nucleus in addition to the cytosol. p94/CAPN3 binds to gigantic muscle protein, connectin/titin, specifically through the region close to IS2. The protease activity of p94/CAPN3 is suppressed *in vivo*, at least partly by binding to connectin/titin N2A region, where other important subcellular structures of muscle, such as sarcoplasmic reticulum and T-tubules, are aligned.

Some alternative splicing products (Lp82, Up86, etc.) of *Capn3* are expressed in tissues other than muscles. Lp82 showed lens-specific expression and Ca^{2+} -dependent protease activity against β A3 and α B crystallins. The activity is inhibited by E-64, but not by calpastatin. Some other splicing variants are expressed ubiquitously, and in embryonic skeletal muscles, although the physiological functions of these variants remain clear.

In 1995, mutations in CAPN3 were shown to be responsible for limb-girdle muscular dystrophy type 2A (LGMD2A), also called 'calpainopathy'. Positions of the mutation found in the LGMD2A patients were distributed widely within CAPN3, with more than half of the mutations being missense mutations (see Figure 3). No hot point was found, making its diagnosis very difficult. A primary cause of LGMD2A is a defect in protease activity, and not structural property, of p94.

nCL-2 and nCL-2' (CAPN8)

nCL-2 and nCL-2' are alternative splicing products of *Capn8*, with and without, respectively, domains III+IV. They are predominantly expressed in the stomach with lesser amounts

in intestines. nCL-2/CAPN8 is highly similar to mCL/CAPN2 along the whole molecule (*c.* 62% identical). Moreover, CAPN8 and CAPN2 are closely located, and their transcripts have overlap, that is, complementary sequences. Recombinant nCL-2 and nCL-2' proteins were expressed in *Escherichia coli* and showed Ca^{2+} -dependent caseinolytic activities. *Xenopus laevis* possesses an nCL-2 ortholog, xCL-2, the disruption of which causes severe developmental defects. Unlike m-calpain, however, nCL-2 does not form a hetero-dimer with 30 K, but instead has activity as a monomer and also forms homo-oligomer via domain III *in vitro*.

nCL-4/CAPN9

nCL-4/CAPN9 is also a typical calpain homolog that is predominantly expressed in the gastrointestinal tract. It possesses overall similarity to μ CL/CAPN1 and mCL/CAPN2 and requires 30 K/CAPNS1 for its activity *in vitro*. Recombinant human nCL-4+30 K protein showed Ca^{2+} -dependent caseinolytic activity, which was inhibited by calpastatin and other cysteine protease inhibitors, as in the case of conventional calpains. nCL-4 is reported to be involved in tumor suppression.

Transform genotypic hermaphrodites (TRA-3) and its orthologs

TRA-3 is involved in the sex determination cascade of *C. elegans*. Although enzymatic characterization of the purified enzyme has not yet been reported, protease activity of TRA-3 is Ca^{2+} -dependent and necessary for female development in XX hermaphrodites through the processing of TRA-2A membrane protein. Interestingly, TRA-3 as well as another *C. elegans* calpain, CLP-1, is also involved in neuronal cell necrosis in cooperation with aspartic proteases ASP-3 and ASP-4. Mammals possess two orthologs of TRA-3, hTRA-3/CAPN5 and CAPN6, whose amino acid sequences are more than 30% identical to that of TRA-3. The T domain, which is conserved in all three molecules, has weak similarity to the C2-domain and, thus, they belong to the tandem C2 PalB subfamily described below. Surprisingly, CAPN6 apparently has no active site residues (active site Cys is substituted with Lys), strongly suggesting that CAPN6 has no proteolytic activity. CAPN6 was reported to be involved in the regulation of microtubule dynamics.

Cpl1, PalB, and its orthologs (PalB subfamily)

Cpl1 is the only calpain homolog found in *S. cerevisiae* and is considered both structurally and functionally to be the ortholog of *Aspergillus* PalB, which plays important roles in the adaptation of fungi to alkaline conditions. *CPL1*, also referred to as *RIM13*, is involved in both the alkaline adaptation and sporulation process of yeast through its processing activity. Rim101 and the *Aspergillus* ortholog PacC, are *in vivo* substrates for Cpl1 and PalB, respectively, and activated by their C-terminal processing. Several other yeasts such as *Candida albicans* and *Pichia pastoris* also have Cpl1 orthologs. In the C-terminus of domain III, Cpl1, PalB, and their orthologs share a somewhat conserved domain, which also has weak similarity to the domain III. Thus, they have two C2-like domains tandemly. Mammals have one ortholog, PalBH/CAPN7, whose physiological functions are elusive, but its involvement in membrane trafficking around endosomes is suggested according to the biochemical studies and analogy to yeasts and fungi.

Calpain 10/CAPN10

This homolog was identified by reverse genetics of non-insulin-dependent diabetes mellitus (NIDDM), type 2 diabetes. The single nucleotide polymorphism (SNP) in intron 3 of *CAPN10* is statistically related to a risk of NIDDM. This SNP may affect transcription levels of *CAPN10*, although direct relationship between CAPN10 and NIDDM has not yet been elucidated. *CAPN10* generates several alternative splicing products. The longest, CAPN10a, has two C2-like domains moderately and weakly similar to that of domain III and, thus, CAPN10a also belongs to PalB subfamily. The physiological roles of calpain 10/CAPN10 are unclear.

SOL and its orthologs (SOL subfamily)

The *Drosophila* gene responsible for a defect in neuronal cells (small optic lobes) corresponding to mammalian retina was positionally cloned and shown to encode a calpain homolog with several Zn-finger motifs located at the N-terminus. Mammals possess one ortholog, SOLH/CAPN15, while *C. elegans* has several. They share a conserved C-terminal structure called the SOL homology domain (SOH).

Defective kernel 1 (DEK1) and its orthologs (DEK1 subfamily)

The maize *defective kernel 1* gene required for aleurone cell development in the endosperm of maize grains encodes a plant calpain homolog. The primary structure of DEK1 is unique in that it has 21 transmembrane regions located at the N-terminus and a C2-like domain, significantly similar to domain III, located at the C-terminus. Rice, *Arabidopsis*, and loblolly pine have very conserved orthologs (above 70% identity), and the whole genome sequence of *Arabidopsis* has revealed that DEK1 is the only calpain homolog in the genome. DEK1 plays a key role in growth regulation in *Arabidopsis*, and although full-length DEK1 protein localizes to membranes, it undergoes intramolecular autolytic cleavage events that release the calpain domain into the cytoplasm, which is sufficient for full complementation of *dek1* mutants.

Other calpain homologs

As described with the TRA-3 subfamily, some of the calpain homologs possess substituted residues in one of the very conserved active site residues, Cys, His, and Asn. Besides CAPN6 and *Drosophila* CALPC, some of the *C. elegans* homologs and all of the trypanosome homologs, do not possess one or more of the active site residues. These molecules are thought not to possess Cys protease activity. Some of the *C. elegans* calpain homologs possess Gly-rich sequences, which is a characteristic of domain V of the calpain regulatory subunits (CAPNS1 and CAPNS2). Trypanosome calpains have N-terminal domains weakly similar to calpastatin. The physiological significance of these structural features has yet to be determined.

Conclusion

This article introduces unique characteristics of various members of the calpain superfamily, mainly from the viewpoint of structure. Various calpains are involved in a variety of biological events and, thus they, if not properly carried on, cause lethality or diseases. Precise molecular roles of most

calpains, however, are still elusive. Prospective approaches for a breakthrough in the field of calpain include studies using genetically modified living organisms such as yeasts, plants, nematodes, drosophila, and mice. These rapidly developing methodologies are revealing novel relationships between calpain and other molecules, which will lead to elucidation of physiological functions of the calpain superfamily at the molecular level.

Carbohydrate Chains: Enzymatic and Chemical Synthesis

T J Tolbert, Indiana University, Bloomington, IN, USA

C-H Wong, The Scripps Research Institute, La Jolla, CA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Anomeric carbon The carbon of a cyclic sugar which forms a hemiacetal or hemiketal. In the linear form of the sugar, the carbon that will become the anomeric carbon when the sugar cyclizes is the carbonyl carbon.

Anomeric effect The stabilization of axial orientation over equatorial orientation of electron withdrawing groups attached to the C1 of pyranose sugars.

Anomers The pair of diastereomers, termed the α - or β -anomer, that results when a linear sugar forms a cyclic hemiacetal or hemiketal.

Glycosidic linkage The linkage formed between the anomeric carbon of a sugar and an alcohol.

Difficulties in the Synthesis of Carbohydrate Chains

The synthesis of oligosaccharides can present several technical difficulties that do not occur in the synthesis of other biopolymers. Unlike nucleic acids and proteins, the linkage between each subunit (i.e., sugar) of a carbohydrate chain forms a chiral center at the sugar's anomeric carbon that has two possible configurations, termed the α - or β -anomer (Figure 1(b)). Each time a sugar is joined to a carbohydrate chain through a glycosidic linkage, the stereochemistry of the bond that is formed must be controlled or directed in some manner to ensure that the correct anomer is produced. In addition, carbohydrate chains are not just simple linear chains as DNA and proteins are, but can also be branched chains with increased complexity. Glycosidic linkages can be formed through each hydroxyl of a sugar, and when multiple hydroxyls on a single sugar form glycosidic linkages, branched oligosaccharide structures result. Distinguishing between the different hydroxyl moieties on sugars is another difficulty of carbohydrate chain synthesis. Each sugar of a carbohydrate chain can have several hydroxyl moieties that are nearly equivalent in chemical reactivity, making them difficult to differentiate from one another and adding several steps to most chemical syntheses. To overcome these difficulties, several enzymatic and chemical methods have been developed.

Enzymatic Synthesis of Oligosaccharides

Enzymes have frequently been employed to synthesize carbohydrate chains, because they offer a few technical advantages over traditional organic synthesis. Enzymes generally do not require protecting groups to select the correct chemical moiety on their substrates, and in carbohydrate chain synthesis this is a great advantage. The many nearly chemically equivalent hydroxyl moieties of sugars make selective chemical protection of sugar hydroxyls a laborious task. The use of enzymes in carbohydrate chain synthesis can eliminate the need for both selective hydroxyl protection before forming the glycosidic linkage, and removal of the protecting groups after forming

the glycosidic linkage, greatly reducing the number of steps required for synthesis of an oligosaccharide. Another advantage of the use of enzymes in carbohydrate chain synthesis is the stereoselectivity of glycosidic bond-forming enzymes, which often produce a single anomer during the formation of a glycosidic bond. By contrast, chemical methods frequently produce mixtures of anomers during glycosidic bond formation, which must be purified from one another after formation of the glycosidic bond. Though enzymatic synthesis of oligosaccharides has many advantages, it is often limited by the availability of specific enzymes needed to form certain types of carbohydrate structures, but with the increased number of enzymes being discovered by genomic research this should improve in the future. Two classes of enzymes that have been used to form carbohydrate chains will be discussed further below, glycosidases and glycosyltransferases.

Carbohydrate Chain Synthesis Utilizing Glycosidases

Glycosidases are enzymes that normally break glycosidic bonds during glycoprocessing or catabolism of oligosaccharides, but by placing glycosidases under certain controlled reaction conditions they can be utilized to form, rather than break, glycosidic bonds. Most often, glycosidases are used to form glycosidic bonds in transglycosylation reactions, where a glycosidic bond is broken in a glycosyl donor glycoside, and a new glycosidic bond is formed with a glycosyl acceptor (Figure 2(a)). Several approaches can be utilized to favor formation of the desired glycosidic bond, including the use of activated glycosyl donors such as *p*-nitrophenyl glycosides, elevated concentrations of glycosyl donors and acceptors, and organic cosolvents. The use of glycosidases to form glycosidic bonds generally results in low to medium yields ranging from 20% to 40%, although yields as high as 90% have been reported using mutated glycosidases. Glycosidase-catalyzed synthesis generally has good stereoselectivity, forming a single α - or β -anomer, but sometimes has low regioselectivity for the different hydroxyls on the acceptor sugar resulting in multiple products being formed.

Figure 1 Carbohydrate chains: (a) some biologically important oligosaccharides and (b) 1-*O*-methyl-glucopyranosides, α - and β -anomers.

Figure 2 Enzymatic synthesis of oligosaccharides using: (a) glycosidases and (b) glycosyltransferases.

Though glycosidase reactions can suffer from low yield and low regioselectivity, there is a wide range of glycosidases available to catalyze the formation of many different types of glycosidic linkages.

Synthesis of carbohydrate chains using mutated glycosidases

Mutation of key amino acid residues in the active sites of many glycosidases can reduce or abolish glycosidic bond cleaving activity while retaining the ability to conduct transglycosylation reactions with natural oligosaccharides or activated glycosyl donors. Such mutated glycosidases are often called glycosynthases in reference to their greater transglycosylation

activities. Using glycosynthases with activated donors has resulted in yields as high as 90% for the formation of glycosidic bonds. Directed evolution is currently being applied to many recombinant glycosidases to expand the range of glycosynthases available for the synthesis of carbohydrate chains.

Carbohydrate Chain Synthesis Utilizing Glycosyltransferases

Glycosyltransferases are enzymes that catalyze the transfer of activated monosaccharide donors to carbohydrates during the biosynthesis of oligosaccharides. They are very useful in synthesizing oligosaccharides *in vitro* because they exhibit high

regioselectivity and stereoselectivity in the formation of glycosidic bonds. Glycosyltransferases that utilize nucleotide sugars as activated monosaccharide donors have often been used in the *in vitro* synthesis of carbohydrate chains (Figure 2(b)). A wide variety of oligosaccharide structures can be produced using the available glycosyltransferases and activated nucleotide sugars such as UDP-glucose (UDP-Glc), UDP-*N*-acetylglucosamine (UDP-GlcNAc), UDP-galactose (UDP-Gal), UDP-*N*-acetylgalactosamine (UDP-GalNAc), UDP-glucuronic acid (UDP-GlcUA), GDP-mannose (GDP-Man), GDP-fucose (GDP-Fuc), and CMP-sialic acid (CMP-NeuAc). Generally, each glycosyltransferase is selective for a specific nucleotide-sugar donor, and also has specificity for certain oligosaccharide structures in its substrates. Because of this it is often difficult to make unnatural oligosaccharides using glycosyltransferases, but in some cases relaxed substrate and nucleotide-sugar specificity has been utilized to make unnatural carbohydrate chains. Formation of oligosaccharides with glycosyltransferases requires the substrate oligosaccharide, a divalent cation, the nucleotide-sugar donor, and the glycosyltransferase itself in an appropriate buffer. Glycosyltransferase-catalyzed synthesis of carbohydrate chains usually results in high yields, approaching 100%, but the enzymatic reaction can suffer from product inhibition that has to be overcome to achieve those high yields. The use of glycosyltransferases in oligosaccharide synthesis is limited by the high cost of nucleotide sugars and the availability of glycosyltransferases that form certain oligosaccharide structures. Sugar-nucleotide recycling alleviates some of the former problem while genomic sequencing and research has started to alleviate some of the latter problem.

Product inhibition in glycosyltransferase reactions

Though glycosyltransferases can be used to form oligosaccharides in nearly 100% yield, they suffer from product inhibition from the nucleoside diphosphates and nucleoside monophosphates that are produced as the activated nucleotide-sugar donors are transferred to the growing carbohydrate chain. This product inhibition can drastically slow the enzymatic reaction and also reduce the yield of product, and so it is desirable to remove the nucleotide by-products of the glycosyltransferase reactions. Two approaches can be used to overcome product inhibition in glycosyltransferase reactions, use of phosphorylases and nucleotide-sugar recycling (Figure 2(b)).

Reduction of glycosyltransferase inhibition with phosphorylases. Nucleoside diphosphates and monophosphates can be converted into nucleosides, which do not inhibit glycosyltransferases, using phosphorylases. This is a very simple method, which requires only one or two additional enzymes to be added to the glycosyltransferase reaction. Unfortunately, this method requires a stoichiometric amount of nucleotide-sugar donor for the formation of the desired oligosaccharide, which can be quite costly on larger scales since nucleotide sugars are generally very expensive.

Reduction of glycosyltransferase inhibition with nucleotide-sugar recycling. Another method to remove nucleotide by-products of glycosyltransferase reactions is to regenerate the nucleotide-sugar donors from the nucleotide by-products using an enzymatic recycling reaction. This method of overcoming product inhibition is somewhat more complicated than using

phosphorylases, requiring several additional enzymes for the nucleotide-sugar recycling reaction, but it allows a catalytic amount of nucleotide-sugar donor to be used in the glycosyltransferase reaction. Since nucleotide-sugars are generally expensive, this method is desirable for larger-scale glycosyltransferase reactions.

Recombinant expression of glycosyltransferases

Genomic sequencing efforts have made the DNA sequences of many mammalian and bacterial glycosyltransferases freely available. This has enabled efforts to recombinantly overexpress glycosyltransferases for use in the synthesis of carbohydrate chains. The use of bacterial and yeast expression systems has allowed several mammalian glycosyltransferases to be produced on relatively large scale, and it has also been recognized that many bacterial glycosyltransferases, which are often easier to express, can be utilized to produce mammalian-type carbohydrate structures. These efforts are ongoing and are continually increasing the range of carbohydrate structures that can be formed using glycosyltransferases.

Chemical Synthesis of Oligosaccharides

Chemical synthesis of oligosaccharides is often the method of choice for constructing carbohydrate chains because chemical methods are flexible, can be used to produce both natural and unnatural oligosaccharides, and are also not limited by the availability of specific enzymes. Formation of glycosidic bonds by chemical methods usually relies upon activation of a leaving group on the anomeric carbon of a glycosyl donor with a Lewis acid, which once activated will react with a free hydroxyl upon a glycosyl acceptor (Figure 3(a)). A wide variety of glycosyl leaving groups have been utilized for carbohydrate chain synthesis some of which are shown in (Figure 3(b)).

Control of Stereochemistry in Chemical Glycosidic Bond Formation

Control of the stereochemistry of the anomeric linkage in the products of glycosylation reactions can be very complex, and many factors including types of protecting groups on the sugars, solvent, temperature, and leaving groups can be used to influence the α/β ratio of the products formed in glycosylation reactions. In general, the anomeric effect, stabilization of axial orientation over equatorial orientation of electron-withdrawing groups attached to the C1 of pyranose sugars, can be utilized to produce α -linked glucosides and galactosides. Participation of protecting groups of the 2-OH, such as acetate, and the use of polar solvents in glycosylation reactions can direct products toward β -linked glucosides and galactosides through dioxocarbenium or solvent intermediates (Figure 3(a)). Other methods for controlling the stereochemistry of glycosidic bond formation include tethering glycosyl donors to glycosyl acceptors and utilization of protecting groups to direct stereochemistry through steric and electronic effects. Sometimes it is difficult to obtain the desired anomer using chemical synthesis, as in the case of sialic acid glycosides,

Figure 3 Chemical glycosylation reactions. (a) Mechanism of glycosylation. (b) Some commonly used glycosylation leaving groups and the reagents used to activate them (in parentheses). Abbreviations: L, leaving group; R, variable group; TMSOTf, trimethylsilyl triflate; NIS, *N*-iodosuccinimide; TfOH, triflic acid; Et₃SiOTf, triethylsilyl triflate; Tf₂O, triflic anhydride; DMDO, 3,3-dimethyldioxirane; DMTST, dimethylthiosulfonium triflate.

where the natural sialic acid linkage is exclusively the α -anomer, but the β -anomer is obtained from most chemical glycosylation reactions. Controlling the anomeric outcome of chemical glycosylation reactions can still be a difficult problem, and requires several approaches for different types of glycosidic linkages and sugars.

Protection of Sugar Hydroxyls in Chemical Carbohydrate Synthesis

Chemical oligosaccharide synthesis relies heavily upon sugar protecting groups both to distinguish between sugar hydroxyls with similar chemical reactivity and also to control the stereochemical outcome, either α or β , of glycosylation reactions. Because of this, chemical oligosaccharide synthesis typically requires a large amount of protecting group manipulations. Normally, protecting groups must be placed on hydroxyls that are not going to be used to form glycosidic linkages to prevent them from reacting in glycosylation reactions. In addition, the synthesis of carbohydrate chains longer than two sugars requires sugar subunits that can act both as glycosyl donors and acceptors, and this usually requires selective protection and deprotection of the hydroxyls that are to form glycosidic linkages. Selective protection of sugar subunits for glycosylation reactions often requires many chemical steps to produce each selectively protected subunit for the synthesis of an oligosaccharide, and this is one factor that can contribute to the large number of steps required for chemical oligosaccharide syntheses. To make the process of producing protected sugar subunits more efficient, one-pot regioselective approaches are being developed to install orthogonal protecting groups on sugars in a single reaction vessel. These one-pot procedures simplify protecting group manipulations by eliminating time-consuming purification and characterization of intermediates. Some protecting groups commonly used in chemical carbohydrate chain synthesis include benzyl ethers, *p*-methoxybenzyl ethers, *tert*-butyl-diphenylsilyl ethers, *tert*-butyl-dimethylsilyl ethers, allyl ethers, acetate esters, benzoate esters, levulinoyl esters, and dimethyl acetals.

Solution-Phase Chemical Oligosaccharide Synthesis

In conventional solution-phase oligosaccharide synthesis, a donor sugar is activated by a Lewis acid at the anomeric carbon, and then reacted with an acceptor sugar that contains a free hydroxyl. Once the glycosidic bond has been formed, the product disaccharide must be purified away from other glycosylation reaction reagents and side products, and then selectively deprotected to unmask a single hydroxyl so that it can then act as a glycosyl acceptor in the next glycosylation reaction (Figure 4(a)). Purification is often necessary after each glycosylation and deprotection step in the preparation of an oligosaccharide by solution-phase synthesis. When combined with the number of steps necessary to produce selectively protected sugar subunits, the number of chemical steps and purifications necessary to construct even small oligosaccharides can be very large.

Automated Oligosaccharide Synthesis

Because of the large amount of work necessary to construct even relatively small oligosaccharides by solution-phase synthesis, many approaches toward automating oligosaccharide synthesis have been developed in hopes of minimizing the number of chemical steps and purifications required to synthesize oligosaccharides. Two approaches to automated oligosaccharide synthesis will be discussed below: solid-phase oligosaccharide synthesis and programmable one-pot oligosaccharide synthesis.

Solid-phase chemical oligosaccharide synthesis

In solid-phase oligosaccharide synthesis, either the glycosyl donor or acceptor of a glycosylation reaction is attached to the solid phase. The advantage of this is that large excesses of the other components of the glycosylation reaction can be used to increase the rate of the reaction and ensure that it goes to completion, and then rinsed away by simple filtration. This has the potential of increasing the yield of glycosylation reactions and also eliminates many of the laborious

Figure 4 Chemical synthesis of oligosaccharides: (a) solution-phase synthesis, (b) solid-phase synthesis, and (c) OptiMer's programmed one-pot synthesis.

purification steps that are necessary in solution-phase oligosaccharide synthesis (Figure 4(b)). Unfortunately, there are many technical difficulties that must be overcome to successfully apply solid-phase synthesis to the production of oligosaccharides. Solid supports that function well with many solvents must be selected, because a wide variety of solvents are used to affect the outcome of glycosylation reactions. Linkers must be developed that are not sterically hindering for glycosylation reactions, stable to glycosylation conditions, and easily cleaved once the oligosaccharide has been synthesized. Strategies for protecting sugar monomers that allow highly flexible and selective deprotection of sugar hydroxyl groups in the presence of many other protected hydroxyls must be worked out. Since the reaction conditions of glycosidic bond formation can vary widely depending on oligosaccharide structure and the types of glycosidic linkages to be formed, there has been great difficulty in developing broadly applicable general methods for solid-phase oligosaccharide synthesis. Nevertheless, there have been many notable examples of successful solid-phase syntheses, including the synthesis of a dodecasaccharide by both the Nicolaou and Seeberger groups.

Programmable one-pot oligosaccharide synthesis

One-pot reaction approaches that involve conducting several sequential glycosylation reactions in one reaction flask have

been developed to facilitate automated oligosaccharide synthesis. The one-pot approach relies upon using a reactivity profile of protected sugars to determine what sequence of sugars to add to glycosylation reactions to obtain the desired products. Protected sugars are added to one-pot reactions in the order of most reactive to least reactive, thereby controlling the order of glycosidic bond formation during the synthesis of carbohydrate chains (Figure 4(c)). Since it has been shown that the types of protecting groups and type of anomeric activating groups used on sugars can greatly alter the speed at which a sugar will react in a glycosylation reaction, a wide range of reactivities can be obtained for a single type of sugar, allowing wide flexibility in oligosaccharide synthesis using this approach. The one-pot approach greatly reduces the number of steps necessary to construct oligosaccharides and eliminates several tedious purifications by combining multiple glycosylation reactions into a single one-pot reaction. The one-pot approach also minimizes protecting group manipulations by eliminating protecting group manipulations after construction of the building blocks. A large number of *p*-methylphenyl thioglycosides have been synthesized and had their reactivities measured to facilitate the use of this strategy. A computer program, OptiMer, has been developed that uses these *p*-methylphenyl thioglycosides as a set of building blocks to choose from to build oligosaccharides. When a carbohydrate chain structure is entered as input, the OptiMer program will calculate the best set of reactants for the

construction of that carbohydrate chain. Because the programmable one-pot strategy requires a minimum of protecting group manipulations and has a large library of building blocks, a wide range of oligosaccharide structures can be synthesized rapidly using this method.

Glossary

2-Deoxyglucose (2-DG) A glucose analog that can be transported and phosphorylated the same as glucose but essentially cannot be further metabolized. When labeled with ^{14}C or ^{18}F , 2-DG can be used as method for assessing glucose metabolism.

Aerobic metabolism This form of chemical breakdown involves oxygen and results in the more complete oxidative metabolism of a compound. In the case of glucose, oxidative metabolism couples the initial glycolytic pathway with the subsequent passage of pyruvate into the mitochondria where it is further metabolized to CO_2 and H_2O . This oxidation is coupled to the production of NADH and FADH_2 , which are further oxidized by the electron transport chain, which is coupled to the production of ATP. The aerobic metabolism of 1 mol of glucose generates approximately 30 mol of ATP.

Anaerobic metabolism This is strictly defined as the chemical breakdown of a compound in the absence of oxygen. In the case of glucose, glycolysis is an anaerobic sequence of reactions that is responsible for the conversion of glucose to lactate that results in the generation of two molecules of adenosine triphosphate (ATP)/mole of glucose.

Blood–brain barrier Morphologically, the barrier is comprised of the microvascular endothelial cells which are

joined by tight junction proteins, effectively preventing paracellular diffusion/leakage of molecules between the blood to the brain. Functionally, access from the blood to the brain is mediated by specific transporter proteins that transport compounds such as glucose or amino acids across both the luminal (blood side) and abluminal (brain side) membranes of the endothelial cells.

GLUTs A family of 14 facilitative glucose transporters. These transporters have differing affinities and capacities to transport glucose and other hexoses.

Glycogen A polymer of glucose comprised of linear chains of glucose molecules in a 1–4 linkage that are branched by the insertion of a 1–6 glucose linkages. It serves as an energy storage molecule and is found exclusively in astrocytes.

MCTs A family of 14 H^+ - or Na^+ -coupled monocarboxylate-related transport proteins. Only MCTs 1–4 are definitively monocarboxylate transporters.

Pentose-phosphate pathway This pathway, also known as the hexose monophosphate pathway, is an oxidative pathway responsible for approximately 5% of basal cerebral glucose metabolism. Its major functions are to generate NADPH for biosynthetic reactions and the maintenance of the levels of the antioxidant, reduced glutathione levels.

It is also the source of pentoses for RNA and DNA synthesis.

Glucose is central to the energy metabolism of most mammalian cells and it is the primary fuel for the mammalian brain. Unlike peripheral tissues such as heart and muscle, the brain is unable to access other energetic fuels, that is, circulating fatty acids and triglycerides, due to the restricted movement of these compounds across the blood–brain barrier (BBB). The importance of glucose as a metabolite derives from the fact that it is a rich source of energy (i.e., adenosine triphosphate (ATP) production), as the complete oxidation of glucose to CO_2 and H_2O proceeds with a standard free energy change of $-2840 \text{ kJ mol}^{-1}$. Glucose can be stored as multiple hexose units in the form of glycogen, providing a quick source of energy to the cell either aerobically or anaerobically. In addition to providing energetic fuel, glucose serves an anabolic role as a carbon source for numerous metabolic intermediates. In this regard, carbohydrate (glucose) metabolism in the brain is similar to that of peripheral tissues. The major pathways of glucose metabolism in brain are (1) glycolysis to provide three-carbon compounds, pyruvate to be used for biosynthetic purposes or to be oxidized in the tricarboxylic acid (TCA) cycle to generate energy as ATP through oxidative phosphorylation (90% of glucose utilization), or lactate for export; (2) glycogen synthesis for glucose storage; and (3) the pentose phosphate pathway for the formation of reducing equivalents in the form of reduced

nicotinamide adenine dinucleotide phosphate (NADPH) for lipid and antioxidant biosynthesis and nucleotide precursors (Figure 1). Each of these pathways proceeds in the brain as in the periphery. Lactate can be transported either from the periphery into the brain or between neural cells as an additional energy source. However, the brain differs from peripheral tissues in that it has quite unique characteristics that impact on various aspects of glucose metabolism. This article presents a review of cerebral glucose metabolism and the limitations and demands specific to the brain.

The human brain weighs approximately 1 kg which is equivalent to approximately 2% of the total body mass, but at rest it receives 15% of the cardiac output and is responsible for 20% of the total oxygen consumption and energy utilization, that is, a very expensive organ. Unlike most peripheral tissues, the brain requires a continual energy/glucose supply to maintain its level of activity and, unlike liver or muscle, has a limited capacity to store energy as glycogen, roughly equivalent to only 5 min worth in the event of a total cessation of supply. Moreover, the concentration of glucose that the neural cells are exposed to (i.e., the brain interstitial concentration) is approximately 20–30% of that observed by peripheral cells. Thus, given the normal levels of circulating glucose of 4.5–6 mM in humans and somewhat higher in rodents, the

levels of interstitial glucose concentrations range between 1 and 2 mM. During hypoglycemia, circulating levels can drop to 2 mM and the effective interstitial concentration approaches zero. Lactate is an intermediate in the metabolism of glucose and can also be an independent energy source for brain, providing approximately 8% of cerebral energy needs under normal conditions. In contrast to glucose, the circulating and interstitial lactate concentrations are approximately equal at 1 mM and remain in steady state. However, under circumstances where the circulating levels of lactate are increased, such as following intensive exercise, lactate uptake and utilization will increase with a concomitant decrease or sparing in cerebral glucose utilization.

The brain is not as homogeneous a tissue as peripheral organs, and demands for energy in the form of glucose demonstrate profound regional variation as illustrated in Figure 2. The figure depicts regional cerebral glucose utilization (rCMRglu) in rat (Figure 2(a)) and human (Figure 2(b)) brain as measured by the accumulation of isotopically labeled 2-deoxyglucose. This methodology, originally developed by Dr. Louis Sokoloff and colleagues, takes advantage of the inability of glycolytic enzymes to metabolize the glucose analog ^{14}C -2-deoxyglucose (2-DG) beyond the hexokinase product ^{14}C -2-deoxyglucose 6-P, which then accumulates in the cell in proportion to the cells' uptake and metabolism of glucose. The extent of accumulation at steady state

is measured quantitatively and expressed as $\mu\text{mol}/100\text{ g tissue}/\text{minute}$ as illustrated in Figure 2(a). An analogous approach is used to determine activity in human brain (Figure 2(b)), except that ^{18}F -2-DG is used as the glucose analog. ^{18}F is a positron emitter and the accumulation of ^{18}F -2-DG-6-P is then measured by positron emission tomography (PET scanning) in virtual axial sections that are taken through the brain. It is readily apparent from the numerical scales of Figure 2 that the rat brain metabolizes more glucose per gram of tissue/minute than does the human brain. This may well relate to the greater proportion of both white matter and glia in the human brain, which have lower energy demands than neurons. Rates of CMRglu are color coded as depicted in the scales adjacent to each figure, and the regional heterogeneity in glucose utilization and energy demand is apparent in the color variation apparent in both brains.

In addition to its regional heterogeneity, the brain is comprised of different populations of cells, each with profoundly different functions and consequent energy requirements. The major cell types are neurons and glia, including astrocytes, oligodendrocytes, and microglia, as illustrated in Figures 3 and 4. These neural cells are separated from the periphery by the microvascular endothelial cells that comprise the BBB. The BBB endothelial cells are the primary gatekeepers for the brain and all energy requirements must first be fulfilled by the passage of sufficient fuel, predominantly glucose, from the circulation across the two membranes of these cells. Thus, the two important components determining cellular glucose utilization are the energetic demand, that is, the cellular work and the major metabolic pathways, and the supply of the essential nutrients.

Figure 3 illustrates the integral membrane nutrient transporters (glucose transporters (GLUTs) for glucose; monocarboxylate transporters (MCTs) for monocarboxylic acids) that facilitate the uptake (supply) and export of the substrates into and out of the respective cells, while Figure 4 illustrates the metabolic pathways that predominate in each of the cells and constitute the demand.

Figure 1 A diagrammatic representation of the various pathways that glucose and lactate are metabolized in the mammalian brain.

Glucose Transporters

The transport of glucose and other hexoses into most mammalian cells is mediated by the SLC2 family of 14 transport

Figure 2 Cerebral glucose utilization in rat and human brain. The figure depicts a digitized autoradiograph of ^{14}C -2-deoxyglucose uptake/phosphorylation in conscious rat, coronal section (a), and a digitized positron emission derived from ^{18}F -2-deoxyglucose uptake in a virtual axial slice obtained from human brain (b). The color coding reflects the calculated cerebral glucose utilization in the respective slices using the algorithms originally formulated by Sokoloff and colleagues. Kindly provided by Dr. Carolyn Beebe Smith.

Figure 3 Neural localization of glucose and monocarboxylate transporters. The figure depicts the cellular localization of the various glucose (GLUTs) and monocarboxylate (MCTs) transporters.

Figure 4 Neural localization of metabolic pathways for glucose. The figure illustrates the relevant metabolic pathways, originally described in [Figure 1](#), in the respective neural cells with corresponding color-coded arrows, and thickness related to the predominance of that pathway within a given cell.

proteins, GLUT1 to GLUT14, which includes HMIT, the proton-driven myo-inositol transporter. With the exception of GLUT1, which is ubiquitously expressed, the other family members have fairly distinct tissue- and cell-specific patterns of expression. As illustrated in [Figure 3](#), the brain with its

complex cellular heterogeneity expresses most, if not all, SLC2 family members. Much of the data supporting the indicated cellular distribution have been reviewed previously and will not be further discussed here. However, it is important to note that many of the transporters indicated in [Figure 3](#) either are unable

to transport glucose (GLUT5, -6, and -11, and HMIT have very low affinity for glucose) or have very limited localization and concentrations (GLUT2 and -4), whereas for others, their location, ability, or capacity to transport glucose have yet to be fully assessed (GLUT8, -9, and -10). Thus, with all of the above exclusions, the predominant transporters in mammalian brain involved in cerebral glucose utilization are GLUT1 and -3, which are expressed throughout the brain and whose localization and kinetic characteristics are well established. Two molecular forms of GLUT1 have been identified: a 55-kDa form in the endothelial cells and a 45-kDa form in the various glia (astrocytes, oligodendrocytes, and microglia) and choroid plexus. The difference in their relative molecular weight is accounted for by a differing extent of glycosylation, but this additional glycosylation does not appear to alter their protein structure or kinetic characteristics. GLUT3 is expressed predominantly in neurons and is distinct from GLUT1 in that its affinity for glucose is higher (K_m , 2–3 vs. 5–8 mM) and the ability to transport glucose is faster (K_{cat} , 6512 vs. 1166 s^{-1} @ 37 °C). An interesting feature of neuronal GLUT3 is that both messenger RNA (mRNA) and protein levels *in vivo* appear to be regulated in direct relation to changes in neuronal activity and rates of cerebral glucose utilization in several conditions underscoring the importance of glucose to neuronal energy demand.

Monocarboxylate Transporters

Also included in [Figure 3](#) is the cell-specific localization of the relevant MCTs, which are responsible for the transport of lactate, pyruvate, and the ketoacids, acetoacetate, and β -hydroxybutyrate.

The MCTs comprise the gene family SLC16, which has 14 members. However, of these 14 family members, only MCT1–4 have been definitively shown to transport metabolically relevant monocarboxylic acids such as lactate, pyruvate, and the ketone bodies, acetoacetate and β -hydroxybutyrate. Moreover, as illustrated in [Figure 3](#), all four are found in brain although MCT3 expression is limited to choroid plexus, and the pigment epithelial cells of the retina. The localization and kinetic characteristics of the MCTs in brain have been the subject of several reviews, and therefore only a brief synopsis is presented here. MCT1 has a very similar pattern of expression to GLUT1 in that it has ubiquitous tissue expression and is located in glia and endothelial cells in the adult rodent brain. The expression of MCT1 mRNA and protein are strongly developmentally regulated in the rodent brain as it serves as a ketone body transporter, which is an important cerebral substrate during development, as will be discussed later. The extent of MCT2 expression is species specific because, although widely expressed in rodents, expression in human tissue is very restricted. In rodent brain, MCT2 is expressed almost exclusively in neurons and subsequent studies have shown it to be extensively expressed in dendrites and associated with postsynaptic densities. MCT4 has been extensively characterized in highly glycolytic muscle, where it is responsible for lactate export. It is also expressed in chondrocytes, white blood cells, and in placenta, where it exports lactate from the fetal circulation. In rodent brain, MCT4 appears to be localized exclusively to astrocytes. In contrast to the glucose transporters, which transport glucose

by a facilitative mechanism that enables the bidirectional transport of glucose down its concentration gradient until equilibrium is reached, the MCTs transport the ketoacids by a proton-mediated co-transport mechanism. The binding constant (K_s) for the proton is 0.2 $\mu\text{mol l}^{-1}$, which corresponds to a pH of 6.7. As with the glucose transporters, the affinities of the MCTs for the ketoacids differ, with MCT2 having a greater affinity for lactate and pyruvate than MCT1 (K_m lactate 0.7 vs. 3.5 mM, pyruvate 0.1 vs. 0.7 mM) and both having much higher affinities for lactate and pyruvate than MCT4 (28 and 150 mM, respectively). Not included in [Figure 3](#) are the Na^+ -dependent glucose transporter(s) or the Na^+ -dependent MCTs whose presence has been shown in rodent brain but whose localization, concentration, and kinetic properties remain to be clarified.

Cellular Metabolic Pathways

The major energy demand for the brain is to fuel neurotransmission, which involves continual depolarization and repolarization of the neuronal membrane via the ionic pumps, Na^+/K^+ ATPase and Ca^{2+} -ATPase. It has been calculated that these action potentials and postsynaptic effects of neurotransmitters (predominantly glutamate) consume 47% and 34% of the total energy, respectively, with the maintenance of the resting membrane potential consuming a smaller amount (13%); glutamate recycling between astrocytes and neurons requires only 3%. To meet the high energetic demand of the neuron, the majority of the ATP is generated from glucose and lactate via the pathways of glycolysis, TCA, and final oxidative phosphorylation ([Figure 4](#)). The neurons are specifically equipped for this through their high mitochondrial content as well as expression of the neuron-specific GLUT3 glucose transporter ([Figure 3](#)) with the highest transport capacity (K_{cat}) determined to date. Thus, neurons appear to be the best equipped for rapid glucose uptake to meet their needs and it was generally considered that glucose was their major and obligate fuel. However, it has more recently been proposed that this function is actually served by lactate derived from astrocytic glycolysis, referred to as the astrocyte–neuron lactate shuttle (ANLS) which is analogous to the situation in skeletal muscle in which lactate is transferred from white-glycolytic to red-oxidative fibers. However, this situation in brain is quite different from skeletal muscle such that this shuttle may be less relevant under most normal circumstances. Indeed, the neuron has both the greatest energy demand and the capacity to utilize an array of potentially available substrates, including glucose, lactate, pyruvate, the ketone bodies (acetoacetate and β -hydroxybutyrate), and various amino acids, dependent on their relative availability. In support of the utilization of these monocarboxylic acids, the neuron also has the low- K_m and high-capacity MCT2 transporter. The actual ratio of glucose to lactate utilization by the neuron remains somewhat contentious, as is the source of the lactate (neurons or astrocytes) and the extent to which this ratio may be altered in activated versus basal state.

The glial component of the brain is comprised of astrocytes, oligodendrocytes, and microglia and the 45-kDa GLUT1 is the predominant glucose transporter isoform that supplies glucose to all of these cells ([Figure 3](#)). The primary energy-requiring

function of the astrocytes is the maintenance of the extracellular environment, including glutamate uptake for synthesis and recycling back to the neuron as glutamine, that is, the glutamate–glutamine shuttle, and the maintenance of K^+ , osmotic, and pH homeostasis. The astrocytes are the major, if not sole, neural cells that express the enzyme pyruvate carboxylase that is necessary for the *de novo* synthesis of glutamine, which is the precursor for the neurotransmitters, glutamate and γ -aminobutyric acid (GABA). In keeping with their role in maintaining cerebral homeostasis, the astrocyte is the primary site of glycogen synthesis and energy storage as glucosyl units. Thus, the predominant pathways of glucose utilization in the astrocyte are glycolysis to generate lactate for potential export, further oxidation or neurotransmitter biosynthesis via the TCA cycle, and glycogen synthesis (Figure 4). The provision of antioxidants, in the form of reduced glutathione, is also an important component of the homeostatic function of astrocytes and thus they also rely on the pentose phosphate pathway for the generation of reducing equivalents in the form of NADPH. The primary function of the oligodendrocyte is the elaboration and maintenance of the myelin sheath that encases and insulates the neuronal axon. Myelin, which is composed of 80% lipid and 20% protein, is synthesized from fatty acids and cholesterol and requires a supply of the reducing equivalents NADPH generated via the pentose phosphate pathway (Figure 4). The flux through this pathway is greatest during cerebral development and active myelination. It is also during development that the brain is most active in the uptake of the ketone bodies, β -hydroxybutyrate and acetoacetate, which serve as precursors in lipid synthesis, and are transported by MCT1. The third glial cell is the microglial cell, the resident immune cell of the brain. As such, microglia are the only antigen-presenting cells in the brain and initiate and orchestrate an inflammatory cascade in response to a variety of stimuli. Central to this inflammatory response is the generation of reactive oxygen species via a number of NADPH-requiring reactions. Thus, in addition to glycolysis and oxidative phosphorylation for the generation of ATP, the pentose–phosphate pathway is active in microglia as well. In addition to GLUT1, the microglia in human and rat brain express the GLUT5 transporter (Figure 3). GLUT5 is actually a fructose transporter and is active as such in peripheral cells, such as intestinal epithelium. However, there is no significant fructose in the brain; thus, the substrate and function of microglial GLUT5 remain to be determined.

All of the above-mentioned metabolic pathways depend on the delivery of glucose (or alternative substrate) from the circulation to the brain and this is the work of the microvascular endothelial cells that comprise the BBB. The primary energy-requiring functions of these cells are the fueling of the Na^+ - K^+ -ATPase components of the wide variety of active transport systems in the abluminal (brain-facing) membrane. The ATP required to support these transport systems is derived from the oxidative metabolism of glucose and potentially other substrates. The major nutrient transporters of the BBB endothelial cells are GLUT1, which exists at this site as a highly glycosylated 55-kDa form, and MCT1. Clearly, these transporters function both for the bidirectional transport of substrates across the two membranes of the cell, and for the provision of energetic substrate to the endothelial cell itself. Under normal circumstances in the adult brain, the supply of glucose is not limited by the transport capacity in the BBB. However, there are some

notable exceptions, which involve either increased demand and/or reduced supply, such as seizures, hypoglycemia, and cerebral ischemia or stroke. Genetic examples of transport limitation to cerebral glucose utilization are seen in the GLUT1 deficiency syndrome, in which affected individuals have only one allele for the GLUT1 glucose transporter and glucose delivery to the brain is significantly compromised. These individuals can be treated by the provision of an alternate energy substrate in the form of ketone bodies, generated by the ketogenic diet.

The above discussion of cerebral glucose utilization applies to the normal adult brain of a range of mammalian species from rodent to human. Although glucose is also the predominant energetic fuel for the immature brain, there are notable distinctions in both energy demand and substrate supply that characterize cerebral development. The energetic demands of the newborn brain are significantly lower than the adult, as are rates of cerebral glucose utilization, approximating only 10–20% of the adult value at birth in the rat to 50–70% for the human. Since the majority of cerebral glucose utilization is to provide the energy to maintain the resting membrane potential, the magnitude – and regional variation – in glucose utilization is directly related to the extent of connectivity of the brain in the resting state, or the number of active synapses. Thus, energy demand, cerebral blood flow, and substrate (glucose) utilization increase as neurons undergo synaptogenesis and form active connections, which is largely postnatal in the rat but begins prenatally in the human infant. During the early stages of development, energy demand increases coincident with the acquisition of new skills, all requiring the successful connection of neural networks. Measurements of cerebral glucose utilization during human development demonstrate a steep increase from birth to approximately 4 years of age, at which time the values are roughly twice those seen in healthy young adults, and this is roughly maintained over the next 4–5 years, before declining to the adult level. This is because during normal development there is an overproduction of neurons, synaptic connections, as well as neurotransmitters, which decline during the period of synaptic pruning and continues into adolescence. Comparable studies in developing rodents have not observed this pattern of cerebral glucose utilization, but instead demonstrate a steady increase from birth to adulthood. However, measurements of cerebral blood flow and energy utilization in developing rats do reach peak levels at P17 and P14, respectively, reflecting the period of increased activity/synaptic pruning at the end of the period of active brain growth. The discrepancy between the human and rodent data relates to the greater importance of circulating ketone bodies, β -hydroxybutyrate and acetoacetate, as energetic fuels to the rodent brain. Although both human and rodent milk are high in fat and generate a significant level of circulating ketone bodies in the suckling offspring to support biosynthetic and energetic pathways, the levels attained in the rodent are greater and the increased energy utilization is met by a combination of glucose and ketone bodies. The delivery of ketone bodies to the developing brain is facilitated by very high levels of MCT1 in the microvascular endothelial cells of the BBB, which also reach peak levels at P14–17 before declining to adult levels after suckling. The primary adaptation to the increased utilization of ketone bodies appears to be at the

level of the BBB, as the nonvascular levels of both MCT1 and MCT2 in the glial and neuronal cells, respectively (Figure 3), do not decrease after suckling, likely reflecting ongoing metabolic trafficking between cells in the mature brain. The other substrate that is of energetic importance to the neonatal brain is lactate, especially during the first hours to days of life in both humans and rodents, and the high levels of BBB MCT1 will facilitate delivery of this substrate as well. However, by P15 in the rodent, glucose has become the predominant energetic fuel accounting for 57% of total energy supply, compared with 23% and 20% for lactate and β -hydroxybutyrate, respectively.

Summary

The brain is a highly energy-demanding organ that consumes a seemingly disproportionate amount of energy of the whole body. It differs from other organs in the body because of the following:

1. it is highly oxidative and uses glucose as its primary energy source as it is unable to access circulating triglycerides and fatty acids;
2. it has a limited capacity to store energy and does so in the form of glycogen;
3. the basal rate of metabolism is high and thus a continual supply of glucose is necessary to sustain activity;
4. because basal cerebral energy utilization is high, activation produces only twofold increases in metabolic activity, in contrast to muscle where 50-fold increases are observed upon activation, even though the activated metabolic rates are comparable between the two tissues;
5. the brain is a heterogeneous tissue and the various cells that make up the brain have markedly different metabolic demands reflecting their differing cellular activities; and
6. restoration of neuronal membrane potentials represents the major energy demand and the neurons are preferentially equipped with the nutrient transporters GLUT3 and MCT2, which have the highest affinity for the available energy substrates – glucose, lactate, or ketoacids.

Glossary

Carbohydrate response element A DNA sequence within the promoter of a gene to which a specific transcription factor binds in response to excess carbohydrate.

Liver pyruvate kinase An isozyme of pyruvate kinase that occurs mainly in liver.

Transcriptional Activation of the Liver Pyruvate Kinase and the Lipogenic Enzyme Genes

Liver pyruvate kinase (LPK) catalyzes the final step of glycolysis, and generates pyruvate and adenosine triphosphate (ATP) from phosphoenolpyruvate (PEP) and adenosine diphosphate (ADP). Pyruvate is then converted into citrate via acetyl-CoA in the mitochondria and citrate is subsequently metabolized back into acetyl-CoA by ATP-citrate lyase in the cytoplasm. The cytoplasmic acetyl-CoA serves as a substrate for triglyceride synthesis.

The genes encoding LPK and the lipogenic enzymes are upregulated in hepatocytes by a high-carbohydrate diet. A short 88-bp segment (−183 to −97) upstream from the transcription initiation site of the LPK gene, referred to as the major late transcription factor (MLTF) site or glucose responsive element, is sufficient to allow glucose-stimulated induction of the promoter. The MLTF site consists of two CACGGG sequences (E-boxes) separated by five bases which are similar to the consensus-binding site (CACGTG) for the c-Myc and upstream stimulating factor (USF) of transcription factor families. Similar elements have been found in the promoter sites of acetyl-CoA carboxylase (ACC) and fatty acid synthetase (FAS) genes. Many other lipogenic genes likely contain the carbohydrate-responsive element (ChRE) within their promoter sites or other regulatory regions that mediate glucose response. The MLTF sequences have been used to identify and characterize ChRE-binding proteins (ChREBPs), but the identity of the carbohydrate-responsive transcription factor remained elusive for a number of years.

Discovery, Purification, and Identification of a New Transcription Factor that Binds to ChRE of the LPK Gene

The identification and purification of ChREBP, a goal of investigators that remained elusive for decades, was finally overcome using an innovative purification scheme. Conventional nuclear extract preparation methods, which had been widely used, were ineffective. When nuclear extracts were instead prepared using polyethylene glycol, which protected the transcription factor against denaturation and allowed for direct assays of DNA-binding activity, ChREBP was readily detected (Figure 1). Subsequent studies indicated that the expression pattern, regulation, and selectivity of the factor were all consistent with its

assignment as a carbohydrate-responsive transcription factor. ChREBP is activated by a high-carbohydrate diet, but not by high-fat diet or starvation. Its DNA-binding specificity under varying glucose concentrations correlates exactly with LPK promoter activity measured *in vivo*. ChREBP activity is highest in liver nuclei under high glucose conditions, coincident with the expression pattern of the LPK target gene under these conditions. These lines of evidence in summary are consistent with its assignment as cChREBP.

Species and Tissue Distribution of ChREBP and a Human Disease Candidate

ChREBP is highly conserved among human, rat, and mouse with over 80% amino acid sequence identity. Orthologs are also present in *Drosophila* and *Caenorhabditis elegans*. The tissue distribution of ChREBP messenger RNA (mRNA) in mammals in decreasing order is liver, adipose, islets, intestine, kidney, cardiac muscle, skeletal muscle, and brain. A candidate human disease involving ChREBP is the Williams–Beuren syndrome, a disorder due to a chromosomal deletion that removes 17 genes including ChREBP. This syndrome, also known as WBSR 14, is a neurodevelopmental disorder characterized by cardiac and vascular defects, dysmorphic facial features, and mental retardation.

Structure and Function of ChREBP

ChREBP is a large protein (Mr of mouse ChREBP = 94 600 Da) consisting of 864 amino acids. The transcription factor contains several domains including polyproline regions, a basic helix–loop–helix and leucine zipper motif (bHLH/Zip), and a zip domain. In addition, there is a nuclear localization signal motif located near the amino terminus as well as multiple phosphorylation sites (Figure 2). The ChREBP molecule can be divided into two functional domains: (1) the amino-terminal region (amino acids 1–250) containing nuclear/cytosol localization signal sites, two nuclear export signal sites (NES1 and NES2), and a nuclear localization signal (NLS) site, which are responsible for the subcellular localization of ChREBP, as well as glucose sensing capacity; and (2) the carboxy-terminal region of ChREBP containing a bHLH/Zip motif which is responsible for DNA-binding and transcription activity.

ChREBP senses circulating glucose level, and localizes either in the cytoplasm under low glucose conditions, as in the starved state, or in the nucleus under high glucose conditions, as in the fed state. However, the mechanism by which ChREBP senses the glucose level (glucose signaling) is not known, and is a focus of current investigations. A metabolite(s) of glucose, rather than glucose itself, serves as signaling compounds for ChREBP, since non-metabolizable carbohydrates cannot serve in the glucose signaling. For export out of the nucleus under low glucose conditions, ChREBP interacts with

a dimeric form of 14-3-3 protein and forms a heterodimer, which then binds to CRM1 (exportin) and translocates in the cytoplasm. In response to high glucose levels, ChREBP interacts with Max-like protein X (Mlx) to form a heterodimer of ChREBP-Mlx. ChREBP itself or a ChREBP-Mlx heterodimer then complexes with importin α and this complex binds to importin β , allowing for localization to the nucleus and transcriptional initiation of lipogenic genes.

Regulation of ChREBP Activity

Glucose and glucagon are opposing forces in maintaining glucose homeostasis by controlling glucose metabolism via glycolysis, gluconeogenesis, and glycogenolysis/glycogenesis pathways. The regulation of these pathways involves both short-term and long-term mechanisms. The short-term regulation involves controls of key regulatory enzymes by allosteric mechanisms involving metabolites and small ligands, and also includes control mediated by covalent modifications. The long-term regulation of these pathways involves altering the expression of genes encoding these same regulatory enzymes.

One mechanism for regulating ChREBP activity is by post-translational modifications. ChREBP contains multiple phosphorylation sites, whose status can be affected by various hormonal and nutrient stimuli. For example, in cell culture models, ChREBP can be phosphorylated at Ser-196, Ser-626, and Ser-666 by cyclic adenosine monophosphate (cAMP)-dependent protein kinase (PKA), which results in the inhibition of nuclear import and DNA-binding/transcriptional activities. In response to the rise in adenosine monophosphate (AMP), AMP-kinase-mediated modification of Ser-568 also inhibits DNA binding. However, the exact *in vivo* role of these phosphorylation sites, as well as the location of *bona fide* phosphorylation sites, in response to various stimuli is unknown. Nevertheless, phosphorylation of ChREBP renders it inactive.

In contrast to glucagon action, a rise in circulating glucose levels stimulates glucose metabolism and promotes the formation of xylulose-5-phosphate (Xu5P), an intermediate of the pentose phosphate shunt pathway. Xu5P specifically activates protein phosphatase 2A δ (PP2A δ) to dephosphorylate an inactive/phosphorylated-ChREBP, and thereby, activates nuclear localization as well as DNA binding of ChREBP (Figure 3). Xu5P-mediated glucose signaling was first discovered in the dephosphorylation/activation catalyzed by the same protein phosphatase (PP2A δ) of the phosphorylated/

Figure 1 Response of ChREBP to dietary content or cyclic-AMP. (a) Gel-shift analysis of hepatic nuclear factors that recognize the LPK carbohydrate responsive element (ChRE). Rats were either starved (lane 1), or fed a high-fat diet (lane 2) or a high-carbohydrate diet (lane 3). Nuclear extracts were prepared from rat livers and incubated with a radiolabeled oligonucleotide corresponding to LPK-ChRE. Lanes 2 and 3 were equalized for protein loads. Arrows indicate the positions of the DNA-binding complexes containing USF or ChREBP. (b) Effect of cAMP on the DNA-binding activity of ChREBP *in vivo*. Rats were fed a high-carbohydrate diet after starvation, and db-cAMP was then injected via the intraperitoneal method. Rats were sacrificed at 10 and 30 min after the injection, and the DNA-binding activity of ChREBP was examined using a gel mobility shift assay. Acad. Sci.* 98, 9116–9121. National Academy of Sciences, USA.

Figure 2 Schematic representation of ChREBP functional domains. Domains that are present include two nuclear export signal (NES) sites, a nuclear localization signal (NLS) site, a basic helix-loop-helix/Zipper DNA-binding domain, and a proline-rich domain implicated in protein-protein interactions. The amino acids designated P1 (Ser-196) and P2 (Thr-666), which are the residues phosphorylated by cAMP-protein kinase whereas P3 (Ser-568) is the amino acid phosphorylated by AMP-dependent protein kinase. The amino-terminal amino acids 1–251 are responsible for glucose-sensing and nuclear import/export. The carboxy-terminal bHLH/Zip region interacts with Mlx to form a heterodimer, which binds to DNA. With permission from Fukasawa, M., Ge, Q., Wynn, M.W., Ishii, S., and Uyeda, K. (2010) Coordinate regulation/localization of the carbohydrate responsive binding protein (ChREBP) by two nuclear export signal sites. *Discovery of a new leucine-rich nuclear export signal site. Biochem. Biophys. Res. Commun.* 391, 1166–1169.

Figure 3 Stimulus-responsive regulation of ChREBP activity. Phosphorylated ChREBP (inactive form) binds to a 14-3-3 protein, complexes with CRM-1, and then is exported out of the nucleus to the cytosol (red arrows). Exposure of hepatocytes to high glucose conditions results in an increased xylulose 5-phosphate (Xu5P) concentration, the stimulus for glucose signaling, which activates protein phosphatase 2A (PP2A). PP2A dephosphorylates ChREBP (active form) and the dephosphorylated ChREBP subsequently binds to importin α and importin β (green arrows), thereby promoting nuclear translocation. Nuclear ChREBP is further dephosphorylated by PP2A, which promotes DNA binding of ChREBP to the ChREs in the promoters of the ChREBP target genes (LPK and lipogenic enzyme genes). In response to glucagon and high fatty acids, PKA and AMPK activities are increased, resulting in phosphorylation of ChREBP. Phosphorylated ChREBP exhibits decreased DNA-binding activity and is actively exported out of the nucleus back into the cytoplasm (red arrows).

inactive bifunctional enzyme, 6-phosphofructo-2-kinase/fructose-2,6-P₂-bisphosphatase (F6P2K/F26Pase; **Figure 3**).

Fatty acids, especially polyunsaturated fatty acids (PUFAs), are potent inhibitors of glycolysis and lipogenesis in the liver. The molecular mechanism for these observations became evident after the discovery of ChREBP, which stimulates the gene expression of LPK and nearly all lipogenesis enzymes. Elevated PUFA levels cause decrease in glycolysis as well as decreased flux through the pentose shunt pathway, and therefore results in decreased Xu5P concentrations. The reduction in Xu5P leads to increased ChREBP phosphorylation, due to the reduced action of PP2A δ , and consequently inhibition of ChREBP nuclear localization and low transcriptional activity. More recently, it was shown in cell lines that PUFA, but not saturated fatty acids, also accelerates ChREBP mRNA decay and thereby decreases ChREBP protein levels. However, the total amount of ChREBP protein usually does not change in primary hepatocytes or in liver upon feeding fatty acids, although the subcellular distribution of ChREBP may be affected.

An alternative mechanism to explain fatty acid inhibition of ChREBP activities involves AMP-activated protein kinase (AMPK). The first step in short-chain, medium-chain, and long-chain fatty acid metabolism is the activation of fatty acids to fatty acyl-CoA and AMP, a reaction that is catalyzed by acyl-CoA synthetase. During this activation reaction, a 30-fold increase in free AMP activates AMPK, which in turn phosphorylates S568 of ChREBP and thereby inactivates ChREBP DNA-binding activity. The AMP-mediated fatty acid inhibition of ChREBP may be distinct from that of PUFA and may play a functional role under different physiological conditions.

Genetic Ablation Studies of ChREBP-Gene in Mice Reveal the Biological Role of ChREBP

ChREBP^{-/-} mice are viable and have a normal life span. However, deletion of ChREBP decreases gene expression of LPK and all lipogenic enzymes including ATP-citrate lyase, acetyl-CoA

Figure 4 The central role of ChREBP in coupling glycolysis and lipogenesis in the liver. Glucose metabolism yields pyruvate in the final step of glycolysis. Pyruvate is then oxidized in the mitochondria to produce citrate. After citrate is transported to the cytoplasm, it is cleaved to regenerate acetyl-CoA, the substrate for fatty acid synthesis. The key regulatory enzyme in glycolysis, PFK, is activated by fructose-2-P₂ (Fru-2,6-P₂), which is synthesized (and also hydrolyzed) by 6-phosphofructo-2-kinase:fructose 2,6-phosphatase (PF2K-Pase). This bifunctional enzyme is activated by the same glucose signaling mechanism used by ChREBP, activation of PP2A by Xu5P. The final step of pyruvate production in glycolysis is controlled by pyruvate kinase (LPK). The long-term regulation of both glycolysis and fatty acid synthesis, mediated through regulation of LPK and of all lipogenesis enzyme genes respectively, is controlled by ChREBP (shown in red). Production of Xu5P is involved in both glucose signaling and the production of reducing equivalents (NADPH, produced by malic enzyme (ME)), as well as for fat synthesis. With permission from Uyeda, K., and Repa, J.J., (2006) Carbohydrate response element binding protein, ChREBP, a transcription factor coupling hepatic glucose utilization and lipid synthesis. *Cell Metabolism* 4, 107–110.

carboxylase 1, fatty acid synthase, stearyl-CoA desaturase, and LCE elongase (Figure 4). Interestingly, malic enzyme, which generates reduced nicotinamide adenine dinucleotide phosphate (NADPH) required for fat synthesis, is the most significantly reduced lipogenic enzyme. In addition, the expression of a glucose transporter gene (*Glut2*) is significantly reduced. These observations suggest that ChREBP coordinately regulates glucose utilization and fatty acid synthesis by tightly coupling the availability of the substrate, acetyl-CoA, for fat synthesis and the activities of lipogenic enzymes.

ChREBP deficiency results in less severe glucose intolerance, perhaps due to repressed glycolysis. Decreased expression of key gluconeogenic enzymes, glucose-6-phosphatase and PEP carboxykinase, in ChREBP^{-/-} mice suggests that increased glucose and glycogen in these animals does not result from increased gluconeogenesis. ChREBP^{-/-} mice are fructose intolerant because of reduced gene expression of two enzymes involved in the fructose metabolism pathway, namely fructose kinase and triose kinase. Due to these coordinated changes in carbohydrate metabolism and lipogenesis, it is not surprising that the rate of hepatic fatty acid synthesis in intact ChREBP^{-/-} mice is reduced by 65% compared to wild-type age- and gender-matched littermates.

The hepatic energy metabolism of ChREBP^{-/-} mice is also decreased compared to wild-type mice. The pyruvate dehydrogenase (PDH) complex is significantly more active in the ChREBP^{-/-} liver because of reduced PDH kinase (PDK3), which inhibits PDH activity. Greater PDH activity causes stimulation of pyruvate/lactate oxidation and therefore decreased fatty acid oxidation in perfused liver of ChREBP^{-/-} mice. This shift in the substrate in mitochondrial substrate for oxidation eventually leads to a threefold reduction in free cytosolic nicotinamide adenine dinucleotide/nicotinamide adenine dinucleotide phosphate (NAD/NADH) ratio, and a 1.7-fold increase in the free mitochondrial NAD/NADH ratio. The net result of the shift from fat to pyruvate/lactate utilization is a decreased energy state in the livers of ChREBP^{-/-} mice.

ChREBP^{-/-} Mice Crossed with Leptin-Deficient ob/ob Mice

As a result of the intercross of ChREBP^{-/-} mice with ob/ob mice, expression of all lipogenic enzymes was significantly lower compared to ob/ob animals. This results in decreased

fat synthesis and normalization of plasma free fatty acids and triglycerides. The overall weight gain was reduced in the doubly deficient ob/ob:ChREBP^{-/-} mice, which was attributed to decreased food intake and possibly from reduced expression of a hypothalamic appetite-stimulating neuropeptide. Activity of gluconeogenic enzymes also was lower in the doubly deficient mice contributing to lower blood glucose. These results suggest that inactivation of ChREBP reduces fat synthesis and obesity, and also improved glucose tolerance and appetite control, in mice genetically prone to development of diabetes.

Summary

ChREBP is required for both basal- and carbohydrate-induced expression of a number of liver enzymes essential for coordinated regulation of glucose metabolism, fatty acids, and the synthesis of fatty acids and triglycerides *in vivo*. Its regulation involves modifications induced after stimulation of a number of signal transduction pathways in response to dietary and other stimuli. The pivotal role that ChREBP plays in intermediary metabolism places it in a privileged position shared by only a handful of transcriptional regulators. Future advances in our understanding of the molecular and biochemical mechanisms responsible for activation and repression of

ChREBP will have important translational implications for the treatment of human disease states.

Cardiac Excitation–Contraction Coupling

D M Bers and S Despa, University of California at Davis, Davis, CA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Channel inactivation Reduction in current amplitude under sustained depolarization.

Electrochemical gradient The difference in ion concentration and electrical potential from one point to another, so that ions tend to move passively along it.

Fibrillation Incoordinated twitching of the heart muscle fibers.

Inward rectifying channel A channel that conducts inward current (positive charge flows into the cell) better than outward current.

Open probability of a channel The fraction of time the channel stays in the open conformation.

Tachycardia A faster than normal heart rate that occurs when an abnormality in the heart produces rapid electrical signals.

Cardiac Excitation–Contraction Coupling: Interplay between Electrical Activity of the Cell, Cytosolic Ca, and the Myofilaments

Cardiac excitation–contraction (E–C) coupling is the process from electrical excitation of the cardiac muscle to contraction, resulting in the pumping of the blood out of the heart. The normal heartbeat is initiated by an electrical impulse that originates in the pacemaker cells of the sino-atrial node. This electrical impulse then propagates as a wave of depolarization through the atrium and atrioventricular (AV) node and reaches the cardiac myocytes in the ventricle. Here, it triggers an action potential (AP), that is, membrane depolarization that follows a finely tuned waveform. The AP then initiates a complex cascade of events culminating in cell contraction. The ubiquitous second-messenger Ca plays a crucial role in these events as it is the direct activator of the myofilaments, the contractile apparatus of the cardiac myocytes. Cytosolic Ca also participates in shaping the AP. Thus, cardiac E–C coupling is a finely orchestrated interplay between electrical activity of the cell, cytosolic Ca, and the myofilaments.

Cardiac AP

When the wave of depolarization generated in the sino-atrial node reaches a ventricular myocyte, voltage-dependent Na channels open, resulting in the inward flux of Na ions down their electrochemical gradient. This Na current (I_{Na}) causes the upstroke (or phase 0) of the AP (Figure 1). The rapid upstroke of the AP is primarily due to the regenerative activation of I_{Na} ; that is, once the membrane potential reaches a threshold voltage in the -70 to -60 mV range, the activation of Na channels leads to further depolarization, which activates additional Na channels and depolarization and so on. This positive feedback creates a very rapid depolarization (200 V s^{-1}) toward the equilibrium potential for Na. In cardiac myocytes, the peak of the AP typically reaches $+30$ mV or more. Depolarization stops in part because Na channels inactivate rapidly (within a few milliseconds). This constitutes a built-in negative feedback on I_{Na} , which limits the gain in intracellular Na to $6\text{--}15 \mu\text{mol l}^{-1}$. Voltage-gated K channels also open during depolarization, but with some latency. Opening of a special type of K channel, which carries a

short-lived, voltage-gated outward K current called ‘transient outward current’ (I_{to}), is responsible for the early rapid repolarization (the notch or phase 1 of the AP; Figure 1).

During depolarization, Ca enters cardiac myocytes through voltage-dependent Ca channels (mainly long-lasting, or L-type channels) which generates an inward Ca current (I_{Ca}). I_{Ca} activation, combined with the transient nature of I_{to} , delays the repolarization and results in a plateau phase in the AP (phase 2; Figure 1). This plateau phase prolongs the AP duration and distinguishes cardiac APs from the much shorter APs found in neurons and skeletal muscle. The AP in rat and mouse ventricular myocytes has almost no plateau phase because I_{to} is much larger than in other species and consequently there is much greater early repolarization. During the plateau phase present in most mammals other than rat and mouse, the inward and outward currents are nearly balanced. The outward current is carried by delayed rectifier K channels (known as I_{Kur} , I_{Ktr} , and I_{Ks}). At some point, repolarization accelerates greatly and the membrane potential returns to the diastolic level (late rapid repolarization or phase 3 of the AP, Figure 1). Repolarization is favored by inactivation of L-type Ca channels, mainly through a mechanism dependent on Ca concentration at the cytosolic side. This Ca-dependent inactivation is a very local effect and is mediated by calmodulin bound to the carboxyl-terminal of the Ca channel protein. I_{Kr} is particularly important in the accelerating phase of late repolarization. As repolarization proceeds, I_{Kr} deactivates at more negative potentials. Below -30 mV, another K current, the inward rectifying current (I_{K1}), increases with repolarization, again accelerating repolarization. I_{K1} is active at resting membrane potentials and is responsible for stabilizing the potential at about -80 mV until the next wave of depolarization reaches the myocyte (phase 4 of the AP; Figure 1). This resting membrane conductance via I_{K1} channels is responsible for the very negative membrane potential seen in cardiac (and skeletal muscle) myocytes versus other cell types (including sino-atrial and AV node cells in the heart and smooth muscle myocytes and neurons).

Cytosolic Ca and Contraction during Cardiac E–C Coupling

L-Type Ca channels are located primarily in invaginations of the cellular membrane called ‘T-tubules’, where they are

Figure 1 E–C coupling in cardiac ventricular myocytes. Inset shows the time course of an action potential (AP), Ca transient ($[Ca]_i$), and contraction measured in a rabbit ventricular myocyte at 37 °C. SR, sarcoplasmic reticulum; NCX, Na/Ca exchanger; RyR, ryanodine receptor; ATP, ATPase; PLB, phospholamban; I_{Ca} , L-type Ca channels current; I_{Na} , voltage-dependent Na current. Modified from Bers DM (2001) *Excitation–Contraction Coupling and Cardiac Contractile Force*, 2nd edn. Dordrecht: Kluwer.

physically close to Ca channels from the apposing sarcoplasmic reticulum (SR) membrane, the ryanodine receptors (RyRs; Figure 1). The open probability of RyRs depends on cytosolic $[Ca]$. Ca activation begins at submicromolar $[Ca]$, reaches a broad maximum near $100 \mu\text{mol l}^{-1}$ and decreases at very high $[Ca]$ ($5\text{--}10 \text{ mmol l}^{-1}$). Ca entering through I_{Ca} during the plateau phase of the AP locally increases $[Ca]$ in the restricted space between the T-tubules and junctional SR to levels as high as $10 \mu\text{mol l}^{-1}$. This is enough to activate the RyRs and trigger Ca release from the SR, a mechanism called ‘Ca-induced Ca release’. SR Ca release contributes to Ca-dependent inactivation of I_{Ca} . For example, total Ca influx via I_{Ca} is reduced by $\sim 50\%$ (from ~ 12 to $\sim 6 \mu\text{mol Ca/l cytosol}^{-1}$) when SR Ca release occurs. Thus, SR Ca release and I_{Ca} create local negative feedbacks on Ca influx. When there is high Ca influx or release, further Ca influx is turned off. The amount of Ca released from the SR also depends on the SR Ca content. Higher SR Ca load not only intrinsically increases Ca flux rate through the RyRs, but also greatly enhances the fraction of SR Ca that is released for a given $\sqrt{Ca}$ trigger. This is due, at least in part, to a stimulatory effect of high intra-SR free Ca concentration on the open probability of RyRs. At moderately low SR Ca content, I_{Ca} can fail to induce SR Ca release. This may help the SR reload if it becomes relatively depleted. Indeed, low SR Ca release allows more Ca influx via I_{Ca} (less inactivation) and reduces Ca extrusion through Na/Ca exchanger (see below). A decline in SR Ca load, even locally, may contribute dynamically to the turnoff of SR Ca release during E–C coupling. SR Ca content can be raised by increasing Ca influx, decreasing Ca efflux, or enhancing SR Ca uptake (e.g., by adrenergic stimulation or increase

in stimulation frequency, AP duration, I_{Ca} , or intracellular Na level).

Ca-induced Ca release is inherently a positive feedback mechanism, but its turnoff is essential for diastolic refilling of the heart. Two mechanisms contribute to the termination of the SR Ca release: SR Ca depletion (since the concentration of free Ca in the SR modulates RyR gating, see above) and RyR inactivation (or adaptation). There are two types of RyR inactivation, and both depend on intracellular Ca. One is an absorbing inactivation (as in the case of Na channels) where the RyR is unavailable for reopening until it recovers. The second type is called adaptation, in which the RyR relaxes after activation to a lower open probability, but can still be reactivated by a higher $[Ca]_i$. RyR inactivation results in refractoriness in cellular and local SR Ca release events and may be important in minimizing inappropriate SR Ca release events between heartbeats.

The combination of Ca influx and release raises free intracellular $[Ca]$ ($[Ca]_i$), allowing Ca binding to the myofilament protein troponin C, the process that switches on the contractile machinery of the myocyte. The dependence of the contraction force on $[Ca]_i$ is highly nonlinear due to high myofilament cooperativity with respect to $[Ca]_i$. The physiological contraction generates both isometric force (or ventricular pressure) and rapid shortening (to eject blood) when the intraventricular pressure exceeds the aortic pressure. There are two main ways to change the strength of cardiac contraction: (1) by altering the amplitude or duration of the Ca transient and (2) by altering the sensitivity of the myofilaments to Ca. Myofilament Ca sensitivity is enhanced dynamically by stretching the myofilaments (as the heart fills with blood), resulting in a stronger

contraction. This is due, in part, to transverse filament lattice compression upon stretch, which enhances the actin–myosin interaction. This is an important autoregulatory mechanism by which the heart adjusts to altered diastolic filling (the classic Frank–Starling response). Myofilament Ca sensitivity is reduced by acidosis and by elevated phosphate and Mg concentrations (all three of which occur during ischemia). Myofilament Ca sensitivity is also reduced by β -adrenergic activation, but enhanced by caffeine and certain inotropic drugs. The rapid Ca transient kinetics prevent the myofilaments from fully equilibrating with $[Ca]_i$ during a normal twitch (especially in the rising phase). Thus, while contractile strength is indicative of underlying Ca transients, there is a dynamic interplay between Ca and myofilaments during E–C coupling contraction and relaxation.

Relaxation of the Heart

For relaxation to occur, $[Ca]_i$ must decline, allowing Ca to dissociate from the myofilaments. There are four pathways that remove Ca from the cytosol: the SR Ca-adenosine triphosphatase (ATPase), the sarcolemmal Na/Ca exchanger (NCX), the sarcolemmal Ca-ATPase, and the mitochondrial Ca uniporter, which takes Ca up into mitochondria (Figure 1). The last two pathways are collectively known as ‘slow’ Ca extrusion pathways and they have a minor contribution in myocytes from healthy hearts. The SR Ca-ATPase (SERCA) takes Ca back into the SR and thus is essential for the refilling of the SR with Ca. SERCA is under reversible regulation by phospholamban (PLB). Dephosphorylated PLB inhibits SERCA activity by reducing its apparent affinity for Ca, with no effect on the maximum pumping rate. Phosphorylation of PLB during sympathetic activation by either cyclic adenosine monophosphate (cAMP)-dependent protein kinase (PKA) or Ca-calmodulin-dependent protein kinase II (CaMKII) relieves this inhibition, allowing faster twitch $[Ca]_i$ decline and relaxation. Since the SERCA competes better with the Na/Ca exchange for extruding Ca, this also enhances the SR Ca content. Thus, relief of the inhibitory effect of PLB on SERCA is a major contributor to the overall positive inotropic and lusitropic effects of sympathetic stimulation (enhanced contraction strength and faster relaxation).

The NCX transports one Ca ion in exchange for three Na ions and can operate in both Ca efflux (or direct) and Ca influx (or reverse) mode, depending on the internal and external concentration of both Na and Ca, as well as on the membrane potential. High $[Ca]_i$ favors Ca efflux, whereas positive membrane potential and high $[Na]_i$ favor Ca influx. In normal myocytes, under physiological conditions, the NCX works almost exclusively in the Ca extrusion mode, driven mostly by the Ca transient. However, the positive membrane potential during the AP plateau can limit Ca extrusion. When $[Na]_i$ is elevated (e.g., by digitalis glycosides, which block the Na/K-ATPase), the amount of Ca influx through NCX can increase greatly. This will raise the cellular and SR Ca content, resulting in larger Ca transients and therefore enhanced contractility. Indeed, the inotropic effect of increasing $[Na]_i$ is well known. Even a small rise in $[Na]_i$ (e.g., 1 mM) can dramatically increase contractile force.

The relative importance of SERCA and NCX in extruding Ca from the cytosol varies between species. In human, rabbit, dog, and guinea-pig ventricular myocytes, the SERCA pump

removes approximately 70% of the activator Ca, and Na/Ca exchange removes 28%, leaving only ~1% to be removed via each of the slow systems. The amount of Ca which leaves the cytosol by entry into mitochondria is inconsequential with respect to E–C coupling, but slow cumulative changes in intra-mitochondrial $[Ca]$ can stimulate key dehydrogenases that increase nicotinamide adenine dinucleotide (NADH) and ATP production to match increased energetic demands that typically parallel the elevated Ca levels. In rat and mouse ventricle, SERCA function is higher than in rabbit (due to a greater concentration of pump molecules) and Ca removal via Na/Ca exchange is lower, resulting in a balance of 92:7:1% for SERCA, Na/Ca exchange, and slow systems. Thus, mouse and rat ventricle (which also exhibit very spike-like APs) poorly mimic human with respect to quantitative balance of cellular Ca flux.

The amount of Ca extruded from the cell during twitch relaxation must be the same as the amount of Ca entry for each beat; otherwise, the cell would gain or lose Ca (i.e., not be in steady state). Indeed, complementary measurements of Ca influx and SR Ca release during a twitch confirm this expectation in rabbit and rat. L-type Ca channels bring ~10 $\mu\text{mol l}^{-1}$ Ca into the myocyte during the plateau phase of the AP. When NCX removes this Ca, it brings ~32 $\mu\text{mol l}^{-1}$ Na into the cell (due to the 3Na:1Ca stoichiometry). Voltage-gated Na channels also bring in about 8 $\mu\text{mol l}^{-1}$, which means that the total Na entering the myocyte during the cardiac cycle is ~40 $\mu\text{mol l}^{-1}$. This excess Na is then extruded by the Na/K-ATPase to keep the intracellular Na level constant.

Altered E–C Coupling in Failing Hearts

Heart failure (HF) is a syndrome that develops when the amount of blood pumped from the heart is inadequate to meet the metabolic demands of the body. In its early stages, there is a reduction in exercise capacity, but as the syndrome progresses, the heart is eventually unable to pump a sufficient quantity of blood to meet the normal metabolic needs of the tissues, even at rest. HF is associated with a poor prognosis (~50% 5-year mortality rate), and for patients with severe symptoms, there is a nearly 50% 2-year mortality rate. Contractile dysfunction of cardiac myocyte is a main cause of HF, but other factors, such as changes in cardiac structure (dilatation), cell death (apoptosis), altered vascular structure and reactivity, abnormal energy utilization, and neurohormonal disturbances, also contribute to the progression of HF, at least under certain conditions.

Defective cardiac myocyte contractility in HF is generally due to altered cellular Ca handling. Myocyte Ca transients are depressed in HF and this causes systolic dysfunction. A major cause for smaller Ca transients in HF is a lower SR Ca content, while Ca entry via Ca channels and the SR fractional release are generally not altered. Reduced SR Ca load not only directly decreases the amount of Ca available for release but also reduces the fraction of SR Ca that is released for a given I_{Ca} trigger, due to the effect of intra-SR free $[Ca]$ on the open probability of RyRs. There are three factors that result in a reduced SR Ca content in HF (see Figure 2): (1) reduced SERCA function, (2) increased expression and function of NCX, and (3) enhanced diastolic SR Ca leak. Typically, SERCA

Figure 2 Cartoon showing the main alterations in E–C coupling that occur in heart failure myocytes. Modified from Bers DM (2001) *Excitation–Contraction Coupling and Cardiac Contractile Force*, 2nd edn. Dordrecht: Kluwer.

expression is reduced while the PLB level is unaltered in HF, although the extent of PLB phosphorylation is reduced. Therefore, the PLB:SERCA ratio is generally increased and the PLB that is there is more inhibitory. Both factors lower SERCA function in HF. The decreased SERCA activity in HF (typically by ~24–50%) coupled with an increased NCX activity (typically 50–100%) allows NCX to compete better with the SERCA in extruding Ca from the cytosol during relaxation. This brings the overall Ca transported by the SERCA and NCX closer to equal in HF and results in lower SR Ca content. There is a spectrum of increase in NCX and decrease in SERCA expression in individual HF patients, suggesting that there is individual variation as to how much the decrease in SR Ca load in HF is due to increased NCX and decreased SERCA function. Hearts with decreased SERCA and unchanged NCX had diastolic dysfunction, whereas hearts with increased NCX expression and relatively unaltered SERCA had preserved diastolic function. Thus, while downregulation of SERCA and upregulation of NCX both result in a lower SR Ca content and impaired contractility, reduced SERCA function also contributes to diastolic dysfunction (Figure 2). Increased expression and function of NCX not only preserve diastolic function but also lead to a higher propensity for triggered arrhythmias in HF (see below).

Elevated diastolic SR Ca leak also contributes to lower SR Ca content in HF (Figure 2). It has been reported that RyRs are hyperphosphorylated by PKA in HF and this leads to an increased SR Ca leak. However, not all studies agree about hyperphosphorylation. Moreover, PKA-dependent RyR phosphorylation does not enhance diastolic Ca leak via RyR (measured by direct block of leak and also via Ca spark measurements) at constant SR Ca load in control myocytes. RyR2 can also be phosphorylated by CaMKII (which is also bound to the RyR2) and this activates RyR opening and diastolic SR Ca release. CaMKII expression and activity and association with

RyR are increased in HF, and CaMKII blockade, but not PKA inhibition, reduced the diastolic SR Ca leak in ventricular myocytes from rabbits with pressure- and volume-overload-induced HF. Interestingly, CaMKII blockade restored SR Ca content, but only slightly enhanced systolic function. This may be because the increased RyR Ca-sensitivity that caused the leak also enhanced the fractional SR Ca release during E–C coupling. However, this sensitization of RyR to Ca in HF may play a very important role in diastolic dysfunction and triggered arrhythmias (see below). In summary, we think that the systolic dysfunction in HF is due mainly to lowered SR Ca content as a consequence of reduced SERCA function and enhanced NCX function while the enhanced SR Ca leak and NCX function may both contribute to an increased propensity for arrhythmias (Figure 2).

Increased Propensity for Arrhythmias in HF

Although many HF patients die due to pump failure (i.e., the heart cannot pump enough blood to maintain the metabolic processes of the organism), nearly half of all deaths occur suddenly, primarily from ventricular tachycardia degenerating to ventricular fibrillation. Myocytes from both patients with end-stage HF and animal models of ventricular hypertrophy and HF exhibit longer AP, which may be due to decreased outward K currents such as I_{to} or I_{K1} . Slow conduction and heterogeneous repolarization, which have been demonstrated in experimental models of nonischemic HF and in patients with idiopathic dilated cardiomyopathy, could contribute to reentrant arrhythmias in HF. Reentrant mechanisms are responsible for about half of the cases of sustained monomorphic ventricular tachycardia in patients with ischemic cardiomyopathy. In nonischemic HF (as well as in ~50% of ischemic HF cases), ventricular

tachycardias initiate mainly by a nonreentrant mechanism. This mechanism involves triggered activity from either delayed afterdepolarization (DAD) or early afterdepolarization (EAD) (triggered arrhythmias).

DADs are initiated by spontaneous SR Ca release at diastolic membrane potentials causing a Ca-activated transient inward current (I_{ti}), which depolarizes the membrane toward the threshold for a triggered AP. The depolarizing I_{ti} is mediated mainly by the NCX, although a nonspecific cationic current and a Ca-activated chloride current had once been thought to be involved in I_{ti} . DADs are more common at high heart rates, because the SR Ca content, and thus the propensity for spontaneous Ca release, is elevated. EADs typically occur in the setting of prolonged repolarization due to alterations in K or Na currents (e.g., long QT syndromes, hypokalemia, and class III antiarrhythmic agents), and also occur in failing myocytes. EADs generally result from reactivation of L-type Ca current, especially when the AP is prolonged. These early EADs occur early during repolarization (during the plateau phase of the AP) and are favored at very low heart rates. However, EADs have also been observed at rapid heart rates. These late EADs generally occur late during repolarization, when the membrane potential is below -40 mV, and are produced by the inward current generated by spontaneous SR Ca release. This mechanism is similar to that leading to DADs occurrence, except that the SR Ca release occurs during the AP.

Although both DADs and EADs have been reported in HF, the nonreentrant initiation of ventricular tachycardias in HF generally involves DADs, whereas EADs are less prominent. This is because EADs generally occur at low heart rates, whereas most ventricular tachycardias in HF occur at more rapid rates (although bradyarrhythmic deaths in HF have also been reported). Second, although hypertrophied and HF myocytes exhibit prolonged AP duration (vs. controls) at low pacing rates, these differences are minimal at more rapid (and physiologic) heart rates at which ventricular arrhythmias occur.

There are alterations in Ca handling and ion channels in HF that could contribute to the increased propensity for DADs despite reduced SR Ca content (Figure 2). When a spontane-

ous SR Ca release occurs, the upregulated NCX in HF causes more inward I_{ti} (NCX current) for a given SR Ca release. There is also a large reduction in the inward rectifier K current that is responsible for stabilizing the resting membrane potential (I_{K1}), which means that any given I_{ti} will cause more membrane depolarization. These changes in NCX and I_{K1} combine to increase the likelihood that an SR Ca release event will induce a DAD that is sufficiently large to trigger a full AP.

Glossary

Carnitine A water-soluble small molecular-weight compound derived from the essential amino acids, lysine and methionine, and is involved in reversible transesterification reactions with acyl-CoAs of different chain lengths. It serves as a general transport vehicle for activated fatty acids.

CoASH Coenzyme A is a cosubstrate of all acylcarnitine transferases catalyzing the reversible transesterification as

well as of numerous other enzymes central to energy metabolism.

Mitochondria Eukaryotic organelles that are surrounded by an inner and an outer membrane and are the sites of energy production.

β -Oxidation A series of enzyme reactions within the mitochondria, called mitochondrial matrix, in which fatty acids are progressively chain-shortened by the removal of two-carbon units as acetyl-CoA.

Carnitine (structure in [Scheme 1](#)) is derived from the essential amino acids, lysine and methionine, is ubiquitous in nature, and is found in especially high concentration in muscle tissue of higher organisms. It functions as a transport vehicle for activated fatty acids of different chain length through membranes within the cell. This transport function is best characterized in mitochondrial oxidation of long-chain fatty acids. This latter process, also known as mitochondrial β -oxidation, represents the repetitive oxidative cleavage of long-chain fatty acids into two carbon units, acetyl-CoA. Acetyl-CoA is then either further oxidized for energy production (all tissues) or used to synthesize ketone bodies (liver) as metabolic fuel for peripheral tissues.

Carnitine Biosynthesis and Homeostasis

The first clue about the physiological function of carnitine came from studies in the mealworm, *Tenebrio molitor*, which suggested that carnitine plays a vital function in fat catabolism. However, carnitine is not a vitamin for higher animals; the daily need is met by endogenous synthesis and dietary intake, mostly from meat products. For endogenous synthesis, the ultimate precursors are the essential amino acids, lysine and methionine. Protein-bound lysine is methylated to trimethyllysine using S-adenosylmethionine, and following liberation by proteolysis, the free trimethyllysine is converted (mostly in muscle) by a series of reactions to butyrobetaine, the ultimate carnitine precursor. Although most tissues are capable of synthesizing butyrobetaine, the hydroxylation of butyrobetaine to carnitine is restricted to the liver (and to a lesser extent to the kidney and brain). Following release of carnitine from the liver into the plasma, carnitine is taken up by other tissues by a carrier-mediated transport process ([Scheme 2](#)).

The body distribution of carnitine is determined by a series of systems that transport carnitine into cells against a concentration gradient, an independent efflux process, and an exchange mechanism in a tissue-specific fashion. Under physiological conditions, plasma carnitine concentration is maintained within a narrow range, predominantly by renal clearance, which is determined by the kinetic properties of carnitine transport system in the brush border.

Functions of Carnitine

In higher animals, the only reaction carnitine undergoes is a reversible transesterification with acyl-CoAs catalyzed by carnitine acyltransferases of differing chain length specificities (carnitine acetyl-, octanoyl-, and palmitoyltransferases) ([Scheme 3](#)).

All known functions of carnitine are based on the reversible transesterification with acyl-CoA esters. The physiologically most important and, therefore, the best-studied metabolic pathway in which carnitine plays a significant role is the mitochondrial oxidation of long-chain fatty acids.

Mitochondrial β -Oxidation

Cellular uptake and activation of long-chain fatty acids

Long-chain fatty acids represent a main energy source for many organs, especially for muscle (heart and skeletal) and liver. Since most tissues contain only small amounts of storage lipids, they depend, for energy production, on a continuous supply of fatty acids, mostly from adipose tissue. Following mobilization by lipolysis in adipose tissue and transport in the blood bound to albumin, fatty acids are taken up by the tissues in a process mediated by transport proteins present in the plasma membrane. Once within the cell, free fatty acids are bound to fatty acid binding proteins, which are present in the cytosol in large amounts. Depending on the tissue and its metabolic demand, fatty acids are converted to triglycerides and stored, secreted as very low density lipoproteins (liver), or oxidized in the mitochondria for energy production. Before being directed into storage or oxidation, fatty acids first are activated to acyl-CoA esters. This reaction is catalyzed by long-chain acyl-CoA synthetase, an enzyme present in abundance both in microsomes and in mitochondria. In mitochondria, long-chain acyl-CoA synthetase is associated with the mitochondrial outer membrane and appears to be a transmembrane protein with its active site exposed to the cytosol. This orientation of long-chain acyl-CoA synthetase gives rise to cytosolic production of long-chain acyl-CoAs, which, for their further β -oxidation, must cross both mitochondrial boundary membranes. Although the impermeability of the inner membrane to

metabolites is well known, it is now recognized that the outer membrane is not freely permeable to solutes as was previously thought. A potential route for long-chain acyl-CoAs to cross the outer membrane could be the voltage-dependent, anion-selective channel (VDAC), also called mitochondrial porin, which occurs at high density in the mitochondrial outer membrane and regulates the permeability of this membrane to ions and metabolites (Figure 1).

Mitochondrial uptake of activated fatty acids – the mitochondrial carnitine system

The mitochondrial carnitine system plays an obligatory role in β -oxidation of long-chain fatty acids by providing a means for their transport into the mitochondrial matrix. This transport

Scheme 1 Structure of L-carnitine (4-*N*-trimethylammonio-3-hydroxybutanoate).

Scheme 2 Interorgan relationship in carnitine biosynthesis.

Scheme 3 Reversible transesterification of carnitine catalyzed by carnitine acyltransferases with different chain-length specificity.

system consists of the malonyl-CoA-sensitive carnitine palmitoyltransferase-I (CPT-I) localized in the mitochondrial outer membrane, the carnitine:acylcarnitine translocase, an integral inner membrane protein, and carnitine palmitoyltransferase-II (CPT-II) localized on the matrix side of the inner membrane. In the schema depicted in Figure 1, the catalytic site of CPT-I faces the intermembrane space. In an alternative model, the catalytic site of CPT-I faces the cytosol. In this scenario, the carnitine esters must cross both mitochondrial membranes. In either case, transesterification of long-chain acyl-CoA esters to their carnitine esters by CPT-I commits activated fatty acids to oxidation in the mitochondrial matrix. CPT-I, by virtue of its inhibition by malonyl-CoA, represents a key regulatory site controlling the flux through β -oxidation. Consistent with its central role in mitochondrial fatty acid oxidation, the enzyme exists in at least two isoforms with significantly different kinetic and regulatory properties. The liver isoform displays a higher affinity for carnitine and a lower affinity for the physiological inhibitor, malonyl-CoA, as opposed to the muscle isoform. Long-term regulation of both isoforms is accomplished at the transcriptional level. Short-term or acute regulation is achieved via changes in tissue malonyl-CoA concentration, and for the liver isoform also through changes in the enzyme's sensitivity to malonyl-CoA inhibition.

The long-chain acylcarnitines formed by CPT-I in the mitochondrial outer membrane enter the mitochondrial matrix in exchange for free carnitine catalyzed by the carnitine:acylcarnitine translocase, an integral inner membrane protein. The carnitine:acylcarnitine translocase catalyzes a homologous/heterologous carnitine exchange (in addition to the slow unidirectional carnitine transport) and displays increasing affinity for carnitine esters with increasing acyl chain-length. Experimental data suggest the existence of a single transporter protein with a substrate specificity ranging from free carnitine to long-chain carnitine esters. This is in contrast to the known substrate specificity of the mitochondrial carnitine acyltransferases (carnitine palmitoyl- and acetyltransferase) and implies that, in addition to its role in mitochondrial fatty acid oxidation, the same transporter is also engaged in other functions involving membrane transport of acyl groups.

Figure 1 Schematic depiction of the carnitine-dependent (CN) transport of activated fatty acids into the mitochondrial matrix and of their oxidative chain shortening via the β -oxidation pathway. LCAS, long-chain acyl-CoA synthetase; CPT-I, malonyl-CoA-sensitive carnitine palmitoyltransferase; CN, carnitine; CACT, carnitine:acylcarnitine translocase; CPT-II, malonyl-CoA-insensitive carnitine palmitoyltransferase; VLCAD, very long-chain acyl-CoA dehydrogenase; TFP, trifunctional protein; DH, acyl-CoA dehydrogenase; EH, enoyl-CoA hydratase; HADH, 3-hydroxyacyl-CoA dehydrogenase; KT, 3-ketoacyl-CoA thiolase.

Following the translocation of long-chain acylcarnitines by carnitine:acylcarnitine translocase into the mitochondrial matrix, the carnitine esters are reconverted to their respective CoA esters by CPT-II, thus completing the carnitine-dependent uptake of activated fatty acids. Within the matrix, CPT-II is anchored to the inner membrane as a peripheral membrane protein. The enzyme has been isolated in catalytically active form from a variety of tissues and its physical, kinetic, and immunological properties determined. CPT-II is the product of a single gene and is expressed as the same protein in all tissues within the body. CPT-II is not inhibited by malonyl-CoA, either in its native environment (membrane-bound) or when isolated.

Pathway of mitochondrial β -oxidation

In the fatty-acid oxidation cycle, the activated long-chain fatty acid undergoes a consecutive oxidative chain shortening. Each cycle of this sequence of four reactions results in the removal of two carbon atoms from the fatty acyl residue in the form of acetyl-CoA (Figure 1 and Scheme 4) and two reducing equivalents (flavin adenine dinucleotide (FADH) and nicotinamide adenine dinucleotide (NADH)). Thus, the complete oxidation of palmitoyl-CoA requires seven cycles yielding eight acetyl-CoAs and seven FADH and NADH molecules. Acetyl-CoA is then further oxidized in the tricarboxylic acid cycle to CO_2 and reducing equivalents, each acetyl-CoA yielding three NADH and one FADH molecule(s). The reoxidation of these reducing equivalents in the electron transport chain then produces adenosine triphosphate (ATP). The complete oxidation of one mole palmitic acid thus results in the formation of 131 mol ATP. On a mole basis, this is 3.6-times more and on a weight basis 2.5-times more ATP generated compared with an equivalent amount of glucose.

The first of the four reactions in mitochondrial β -oxidation of activated long-chain fatty acids is catalyzed by the acyl-CoA dehydrogenases, a group of enzymes with differing but somewhat overlapping chain length specificity (very long-chain, long-chain, medium-chain, and short-chain) resulting in the formation of 2-*trans*-enoyl-CoA. They are composed of four identical subunits, each of which contains a non-covalently bound FAD. The enzyme is reoxidized via the electron-transferring flavoprotein and then in the electron transport chain by electron-transferring flavoprotein:ubiquinone oxidoreductase.

The second step of β -oxidation is catalyzed by 2-enoyl-CoA hydratases converting 2-*trans*-enoyl-CoA to 3-hydroxyacyl-CoA.

Scheme 4 Reactions of mitochondrial β -oxidation of saturated long-chain acyl-CoAs.

This reaction is catalyzed by the membrane-bound long-chain trifunctional protein, TFP, formerly known as the long-chain enoyl-CoA hydratase. The TFP comprises two non-identical subunits, the α and β subunits, present in a 1:1 molar ratio. The enzyme comprises the catalytic activities of 2-enoyl-CoA hydratase and 3-hydroxyacyl-CoA dehydrogenase (α subunit) and 3-ketoacyl-CoA thiolase (β subunit). The soluble short-chain specific form, also known as crotonase, catalyzes the hydration of short-chain 2-enoyl-CoAs.

The third reaction is catalyzed by 3-hydroxyacyl-CoA dehydrogenases. At least two 3-hydroxyacyl-CoA dehydrogenase activities are found in the mitochondria. In addition to the TFP, there is also a short-chain-specific form. The latter is composed of two identical subunits. Both activities require NAD as a co-factor. NADH formed is then reoxidized by complex I of the electron transport chain.

The last reaction of the β -oxidation spiral is the thiolytic cleavage of 3-ketoacyl-CoA catalyzed by the enzymes, 3-ketoacyl-CoA thiolases. The general acyl-CoA thiolase and the long-chain 3-ketoacyl thiolase of the TFP have overlapping substrate specificities. The reaction is greatly in favor of product formation. There is also a third thiolase enzyme present in mitochondria, called acetyl-CoA acetyltransferase or acetoacetyl-CoA thiolase. This latter enzyme is specific for acetoacetyl-CoA and 2-methylacetoacetyl-CoA and probably is involved in branched-chain amino acid metabolism, in ketogenesis, and in ketone body utilization.

The oxidation of (poly)unsaturated fatty acids requires auxiliary enzymes for their complete β -oxidation. Most unsaturated fatty acids have their double bonds in *cis* configuration with the first double bond between carbon atoms 9 and 10. Additional double bonds, if any, occur at three-carbon intervals. Several cycles of β -oxidation yields a chain-shortened acyl-CoA with a *cis* double bond in 3, 4 position that is not a substrate for enoyl-CoA hydratase. Isomerization catalyzed by 2,3-enoyl-CoA isomerase leads to 2-*trans*-enoyl-CoA, which can undergo further β -oxidation yielding, after two additional cycles, *trans*-2, *cis*-4-dienoyl-CoA, which is also a poor substrate for enoyl-CoA hydratase. The *cis*-4 double bond is reduced by the enzyme 2,4-dienoyl-CoA reductase producing *trans*-3-enoyl-CoA, which is isomerized to *trans*-2-enoyl-CoA by 2,3-enoyl-CoA isomerase.

The rate of β -oxidation is adjusted to physiological needs and is subject to control in which substrate supply is important. The reaction catalyzed by CPT-I committing activated fatty acids toward oxidation in the mitochondria often is considered rate limiting. The regulatory property that imparts such control to this otherwise near-equilibrium reaction is the inhibition of CPT-I by malonyl-CoA. The muscle isoform of CPT-I is extremely sensitive to inhibition by malonyl-CoA and it is thought that, in heart and skeletal muscle, CPT-I is regulated only by changes in tissue malonyl-CoA concentrations. The liver isoform of CPT-I is much less sensitive to malonyl-CoA inhibition and, in liver, the entry of activated fatty acids into the mitochondria is controlled by changes in the enzyme's sensitivity to malonyl-CoA as well as by changes in hepatic malonyl-CoA concentrations.

Although the mitochondrial uptake of long-chain activated fatty acids is absolutely carnitine dependent, the efficiency of the system is such that, under physiological conditions, tissue

carnitine concentrations seemingly have no significant impact on this process.

The control of β -oxidation flux by the redox state of NAD/NADH and FAD/FADH (electron-transferring flavoprotein (ETF/ETFH₂)) as well as by the acetyl-CoA/CoASH ratio is important under some conditions.

Regulation of Mitochondrial Acyl-CoA/CoA Ratio

The β -oxidation pathway is not the only one in which carnitine plays a role as a carrier of activated acyl groups. In conjunction with carnitine acetyltransferase and carnitine:acylcarnitine translocase, carnitine forms an effective shuttle system for acetyl groups out of the mitochondria, thus preventing sequestration of intramitochondrial free CoASH. This acetyl-CoA buffer function allows CoASH-dependent reactions such as pyruvate oxidation to proceed unimpaired. The CoASH buffer function is not restricted to acetyl-CoA. Under normal physiological conditions, the direction of long-chain fatty acid movement is into the mitochondrial matrix. However, the carnitine:acylcarnitine translocase and CPT-II/carnitine acetyltransferase system can under certain conditions operate in the reverse direction, for example, removing activated short-, medium- and long-chain acyl groups from the matrix. This buffering has been demonstrated with isolated mitochondria, as well as with cultured fibroblasts and lymphocytes from patients with defects in mitochondrial fatty acid oxidation. The accumulation of cellular acyl-CoAs as a result of an inborn error of fatty

acid metabolism leads to a corresponding increase in acylcarnitines in the cell. In contrast to the acyl-CoAs, the acylcarnitines can be transported across the plasma membrane into the blood. The identification of these acylcarnitines in blood is thus a signpost for the metabolic defect.

Glossary

Apoptosis Physiological mechanism of programmed cell death mediated by caspases (cysteine proteases), regulated by the Bcl-2 family of proteins, and triggered from the membrane (death receptors and adhesion), cytosolic stress, or nuclear signals (DNA damage). Excessive or defective apoptosis is involved in diseases such as ischemia, acquired immunodeficiency syndrome (AIDS), neurodegeneration, autoimmunity, and cancer.

Apoptosome Multiprotein complex of 700-kDa molecular weight formed by procaspase-9, apoptotic protease activating factor 1 (Apaf-1), deoxyadenosine triphosphate (dATP), and cytochrome-*c*. It proteolytically activates caspase-9, leading to the activation of downstream effector caspases, and subsequently death of the cell.

Baculovirus IAP repeat (BIR) A protein structural domain, conserved in both mammalian and viral proteins able to interfere with the apoptosome or with the active caspases. It characterizes the IAP proteins.

CysteinyI aspartate-specific protease (caspase) Cysteine proteases which cleave after an aspartate (D). The family

includes 13 enzymes involved either in programmed cell death (apoptosis) or in inflammation.

Death initiation signaling complex (DISC) Multiprotein complex beneath the cell membrane activated by trimeric death receptors (e.g., CD95, TRAIL-R, and tumor necrosis factor (TNF)). It includes the receptor, adaptor molecules, procaspases (caspases 8 and 10), and their related substrates (e.g., Bid) that signal to the mitochondria–apoptosome to activate the caspases, and therefore kill the cell by apoptosis.

Death receptors Cell membrane receptors (e.g., CD95, TRAIL-R, and TNF) belonging to the TNF superfamily, able to activate apoptosis via the formation of a DISC when bound by their specific ligands (e.g., CD95L, TRAIL, and TNF). These are essential in regulating the immune response.

Inhibitors of apoptosis (IAPs) Mammalian or viral proteins able to inhibit the activation of the apoptosome or the active caspases. They are characterized by structural domains called BIR; consequently, all IAP proteins are also called BIR proteins (BIRp).

Apoptosis, a major form of cell death used to remove unwanted or excess cells, is characterized by a plethora of morphological and biochemical changes resulting primarily from the activation of a family of cysteine proteases, which cleave their substrates at specific aspartate residues. Caspases are cysteine proteases involved in cell death. The name caspase is derived from cysteinyl aspartate-specific protease, that is to say proteases which cleave after an aspartate (D). The caspase family is comprised of 13 proteins in human (Figure 1), seven in *Drosophila melanogaster*, and a single protein in *Caenorhabditis elegans*. As depicted in Figure 2, all caspases consist of three structural domains: a prodomain, a large subunit, and a small subunit. The prodomain is important for the regulation of the enzymatic activation of caspases; the active enzyme consists of the small and large subunits together. To obtain an enzymatically active enzyme, the three subunits must be proteolytically cleaved, which is effected by other endoproteases, normally also a caspase. The site of cleavage of the substrate is indicated by the positions P4, P3, P1, and P1, and is always Asp (D) (Figure 3). The other positions are highly variable.

History and Classification

Caspases were first identified in 1989 by Sleath and Schmidt as a protease required for the activation of interleukin 1 β .

In 1993, the group of Bob Horvitz discovered that the cell death gene *ced-3* is a protease belonging to the same family. In 1999, the first human genetic disease caused by mutation of a caspase (type 10) was identified by Michael Lenardo.

Phylogenetic analyses, and also studies of substrate specificity, indicate that caspases can be subdivided into three different groups. Figure 4 reports the present classification of the human caspases.

Group 1 includes caspases 1, 4, 5, and 12, which are involved in inflammation. The prototype of this group is caspase 1, previously known as interleukin conversion enzyme 1 β , or ICE. Its enzymatic activity was identified in 1989, but the enzyme was only purified and cloned in 1992, the same year in which Lois Miller identified the first inhibitor, the viral protein CrmA. Caspase 1, or ICE, controls the maturation of interleukin-1 beta (IL-1 β) actively participating in the inflammatory response. Site P4 of the substrate is preferentially a hydrophobic residue.

Group 2 includes caspases 2, 3, and 7, shown by a star in Figure 4. The prototype of this group is caspase 3, the homolog of *ced-3* in *C. elegans*. Group 2 caspases are directly involved in apoptosis in the terminal effector phases. Group 2 caspases have a very small prodomain, indicating a simple regulation of their enzymatic activation. These caspases are in general activated directly by another caspase, in a cascade of enzymatic amplification. Site P4 of the substrate is preferentially an Asp

(D) residue. Site P3 of the substrate is preferentially a Glu (E) residue. Therefore, this subfamily preferentially cleaves substrates with the sequence DEXD.

Group 3 consists of caspases 6, 8, 9, and 10. These caspases have a very large prodomain, and therefore a complex mechanism of activation. In fact, these caspases need molecular adaptors to be enzymatically activated, in contrast to group 2 caspases. Caspases 8 and 10 are part of the signal transduction mechanism of apoptosis receptors such as CD95; in this case, the adaptor molecule is Fas-associated protein with death domain (FADD; **Figure 3(a)**). Caspase 9 is activated in the apoptosome, and the necessary adaptor molecule is apoptotic protease activating factor 1 (Apaf-1; see **Figure 3(b)**). Site P4 of the substrate is preferentially an aliphatic residue.

Structure and Active Site

As already mentioned, caspases consist of three structural domains: a prodomain, a large subunit (also named as p20), and a small subunit (called p10; **Figure 5**).

The enzyme is constituted of the small and large subunits (p20/p10, around 30 kDa). The active site is in fact in the p20 subunit: it can be further classified into four different subsites

Figure 1 Caspases and cell death. Caspases are the proteolytic enzymes responsible for cell death. They are activated by an adaptor molecule (apaf-1), which in turn are controlled by the Bcl-2 family, and in particular by the BH3-only subfamily and the Bcl2-subfamily. The final stages of activation of the caspase can be regulated by a different pathway, the IAPs. This simple scheme is conserved in evolution from *C. elegans* and *D. melanogaster*.

S4–S1. The S1 subsite, which attacks the carboxyl group of the polypeptide side chain in P1 (the site of cleavage is Asp -D), is composed of p20 as well as p10 subunits. Similarly, the site for recognition and positioning of the substrate (S4–S1) is furnished by both p20 and p10, even though the residues mostly responsible for specificity (S4) are contained in p10 (see **Figure 6**).

Caspases enzymatically function as dimers of two identical molecules bound to each other. **Figure 5** shows a very schematic view of the dimer formation.

Each monomer (p20/p10) is formed by a compact cylinder dominated by six β -sheets and five α -helices distributed on the opposite site of the plane formed by the β -sheets. The dimer (p20/p10)₂ contains two (p20/p10) units aligned head to tail, which therefore position their respective active sites on opposite sides of the molecule. While there are two active sites, their cooperation has never been observed. The orientation of the molecule indicates a specific mechanism of activation, well regulated with security systems (a 'safety catch').

Substrate Recognition

The substrate recognition site of the caspase is indicated as S4–S1, at which the substrate is bound at residues P4–P1 (**Figure 6**). This recognition guarantees an absolute specificity. The S4–S1 substrate recognition site varies in each caspase, even if S1 is absolutely constant and highly tight. This is responsible for the absolute specificity to bind Asp (D) as the substrate residue P4. In fact, Asp is physically constrained and held by a hydrogen bond with Arg179, Gln283, Arg341 (the numbers refer to caspase 3). The dimensions of the S1 subsite are reduced to a minimum, and are therefore responsible for the lack of tolerance for P1 (Arg). Bond sites P2 and P3 (subsites S2 and S3) are more tolerant, less specific, and more heterogeneous in the various caspases. Therefore, the substrate (or the inhibitor) positions itself within the S1–S4 site, creating interactions as hydrogen bonds with Ser339 and Arg341 (conserved in practically all of the caspases). The P4 (S4) binding site is the major determinant of specificity (**Table 1**).

Figure 2 The apoptotic pathways in humans. In mammalian cells, apoptosis can be triggered at three different levels, as indicated. The signal converges to the apoptosome where the final effector phase occurs. Caspases are involved both in the upstream regulatory phase and in the final terminal phase. The regulation at the level of the death receptor, and of the apoptosome, is shown in greater detail in **Figure 3**.

Figure 3 Regulation of the apical regulatory caspases. The general scheme is reported as in Figure 2. (a) Formation of the death-inducing signaling complex (DISC), following the activation of a death receptor such as CD95 (also called Fas or APO-1). Three molecules of ligand (CD95L) bind three molecules of receptor (CD95), allowing the recruitment of the adaptor molecule FADD via their death domain (DD). In turn, FADD, via its death effector domain (DED), recruits and activates caspase 8, which cleaves the specific substrate Bid. Truncated Bid (tBid) is in fact the molecular signal that propagates the death signal to the mitochondria and the apoptosome. This mechanism can be inhibited by the molecule FLIP, via its DED. (b) When activated by apoptotic signals (e.g., by tBid), mitochondria release several molecules, as indicated. In particular, cytochrome *c* goes to the apoptosome (formed by cytochrome *c*, apaf-1, pro-caspase 9, and dATP), and allows the activation of caspase 9. This, in turn, activates several molecules of downstream effector caspases (type 3, 6, and 7), and, consequently, the cleavage of many cellular substrates results in cell death. Still at its terminal stage, cell death can be inhibited by specific inhibitory proteins (IAPs), but another mitochondria-released protein, Diablo/Smac, can remove the protection by IAPs. The cascade of proteolytic amplification created by caspase 9 (apical regulatory caspase) and caspases 3, 6, and 7 (downstream effector caspases) is extremely powerful.

Figure 4 The human caspases family: Classification of the human caspases. According to the phylogenetic tree, caspases are subdivided into two major subfamilies, ICE and ced 3. The former are involved in inflammation, and the latter in apoptosis. The caspases with a very short prodomains (<30 aa) are boxed (type 3, 6, and 7); all the other enzymes have long prodomains (>10 kDa) subject to complex regulation. The enzymes can be divided according to their proteolytic specificity into group I, involved in cytokine maturation, group II, involved in the final effector phase of apoptosis (indicated by a star), and group III, involved in the upstream regulation of apoptosis. At least two gene clusters have been identified, consistent with some caspases arising from tandem gene duplication. Caspase 13 is an error of sequencing; caspase 12 is mutated into a nonfunctional enzyme in up to 90% of the human population. The scheme has been modified from Nicholson DW (1999) Caspase structure, proteolytic substrates, and function during apoptotic cell death. *Cell Death and Differentiation* 6: 1028–1042.

Table 1 Caspase substrates

Bcl 2	caplastatin
Presenilin 2	ataxin-3
Huntingtin	AMPA receptors
SBMA-AR	p27 kip1
Atrofin-1	MCM3

This list of substrates is incomplete; a more comprehensive list of over 1000 substrates, with their role in cell death, is reported in Nicholson (1999) and Fischer et al. (2003). The substrates of caspases can have single cleavage site (e.g., DQTD in Gelsolin), nested multiple sites (e.g., DEVGDVD in PARP), redundant clustered sites (e.g., DSLD-(X13)-DEED-(X16)-DLND-(X32)-DGTD in Huntingtin), or distal multiple sites (e.g., DEPD and DAVD in ICAD). See website CASBAH.

Mechanism of Action

Caspases are cysteine proteases, possessing therefore a catalytic triad which includes a cysteine (active site) in the vicinity of an histidine. The third component of the classical catalytic triad typical of cysteine proteases is not constant in caspases, and its function can be differently substituted by different groups in different components of the family. For example, if we consider caspase 3, subsequent to substrate binding, the catalysis can take place with the catalytic diad Cys285 and His237. The third element of the cysteine protease triad is in fact substituted by an ossianionic bond formed with Gly238 and Cys285 (conserved in all caspases).

Table 2 Peptide inhibitors of caspases

	<i>zVAD-fmk</i>	<i>aDEVd-cho</i>	<i>aYVAD-cho</i>
Caspase 1	2	15	1
Caspase 2	2400	1700	>10 000

Caspase 10	-	10	400

Inhibition constant (K_i , nM) shown is $t_{1/2}$ at 1 μ M in seconds.

The table has been modified from Ekert PG, Silke J, and Vaux DL (1999) Caspase inhibitors. *Cell Death and Differentiation* 6: 1081–1086; see also Nicholson (2000).

Sequence of Action

While the regulatory caspases of the death receptor (type 8 and 10) or of the apoptosome (type 9) participate in signal transmission, the effector caspases (type 3, 6, and 7) determine the death of the cell. Effector caspases are diverse, and are not activated in parallel, but in a sequential manner, resulting in an amplification cascade of proteolytic cleavage (vaguely similar to the cascade of proteolytic activation and amplification of the complement system, or blood coagulation). These cascades have the effect of augmenting the signal. This sequence of activation is somewhat reminiscent of the complement activation or of the coagulation cascade (Figure 7).

In the intrinsic pathway, mitochondrial perturbation results in the release of cytochrome *c* to the cytosol, which, in conjunction with deoxyadenosine triphosphate/adenosine triphosphate (dATP/ATP), causes Apaf-1 oligomerization and caspase-9 activation. Caspase-9 bound within the apoptosome complex to Apaf-1 through their CARD (caspase activation and recruitment domain) domains is two to three orders of magnitude more active than free caspase-9 within the cytosol. In the apoptosome therefore, the first caspase to be activated is caspase 9. Within the apoptosome, caspase-9 processes and activates both caspase-3 and -7 by cleaving between their large and small subunits. Therefore, caspase-9, in turn, activates caspases 3 and 7. Caspase 3 is also able to proteolytically activate caspase 9, thereby creating a reciprocating loop of potentiation. Caspase 3 proteolytically activates caspases 6 and 2. At this point, caspases 3, 7, 6, and 2 are highly activated and work to proteolytically cleave their intracellular substrates and determine cell death itself. Although the initial sequential processing and activation of caspase-9, -3, and -7 are generally well established, the precise hierarchical ordering of other caspases within the caspase cascade is less clear, being subject of current investigations, particularly in cells undergoing apoptosis. A hierarchy of caspase activation was established using a model system of dATP-activated lysates to mimic events following activation of the intrinsic pathway and this paradigm is still believed to hold. Although this model of caspase activation is currently widely accepted, there are some inconsistencies between the model and the phenotype from knockout mice for caspase-3-/-, caspase-7-/-, and

Table 3 Natural caspase inhibitors

	<i>Viral</i>			<i>Cellular</i>

Inhibition constant (K_i , nM) shown is $t_{1/2}$ at 1 μ M in seconds.

NI, noninhibitory; Inib, inhibitory.

The table has been modified from Ekert PG, Silke J, and Vaux DL (1999) Caspase inhibitors. *Cell Death and Differentiation* 6: 1081–1086.

Table 4 Caspase knockouts

	<i>Development</i>	<i>Apoptotic phenotype</i>
Caspase 1	Normal	Inflammation, (CD95?)
Caspase 2	Normal	Germinal cells (stem cells?)
Caspase 3	Lethal PN	Neural
Caspase 6	Normal	
Caspase 7	Lethal E	
Caspase 8	lethal E	Death receptors (CD95, TNF, and DR3)
Caspase 9	lethal E	Neural
Caspase 11	normal	thymocytes, neural (CD95?)

A more comprehensive discussion is reported in Zheng et al. (1999).

Often, the severity of the phenotype depends on the genetic background of the animals, as, for example, described in caspase 3.

E, embryonically lethal; PN, perinatally lethal.

caspase-3^{-/-}/caspase-7^{-/-} double-knockout mice. The double knockout mice died shortly after birth because of a defect in cardiac development and caspase-3 seemed to play a prominent role in DNA degradation, whereas caspase-3 and -7 were important in cell viability. Furthermore, caspase-7^{-/-} mice had a relatively mild phenotype most likely because of compensation from caspase-3 and both caspase-3 and -7 were key mediators of the loss of mitochondrial membrane potential. In agreement with this, we have recently shown that caspase-6 can be processed by caspase-7 in a caspase-3 independent manner in cells undergoing apoptosis in contrast to the *in vitro* model system using dATP-activated lysates (Inue 2009). A diagram of the currently accepted order of activation is depicted in Figure 7.

Caspase 6 can also proteolytically activate the apical regulatory caspases 8 and 10, creating therefore a further loop of potentiation, which further enhances the death receptor signals.

Schematically we can redefine the molecular phases of apoptosis in the following manner (see Figure 7): (1)Initiation, activation of death receptors (caspases 8 and 10); (2) determination, activation of the apoptosome (caspase 9); (3) amplification, increase in the type and number of active caspases (caspases 3, 7, 6, and 2) and apical reactivation loop (caspases

8 and 10); and (4)demolition, proteolytic cleavage of over 1000 different substrates which determine the death of the cell.

Substrates during Apoptosis

Experimental studies indicate that over 700 different polypeptides can be generated during apoptosis. Up to 2003, according to SchultzeOstoff, over 1000 proteins have been found to be cleaved by caspases during the execution of apoptosis. Currently, over 100 substrates of caspases have been identified *in vitro*, or *in vivo*. A new website, named CASBAH, has been created with all specific detailed substrates.

Table 1 indicates some examples of the principal substrates. The proteolytic cleavage of these substrates clearly renders the cell incapable of performing its proper functions.

Inhibitors

For practical reasons, we distinguish pharmacological (Table 2) and natural (Table 3) inhibitors of caspases.

The understanding of the molecular mechanism of catalysis and of the properties of the sites P4–P1 of the substrate was the basis for designating pharmacological inhibitors, both of polypeptide type and of low-molecular-weight compounds. The electrophilic groups which interact irreversibly with the catalytic Cys are aldehydes, nitriles, and ketones, of which the latter are much more stable than the others *in vivo* and therefore are most easily applied to pharmaceuticals. Caspase inhibitors are all constituted according to the following schema: [tetrapeptide]-C)-CH₂-X, where X signifies a –Cl or –F (fluoro- or chloro-methyl ketone, abbreviated fmk), –N₂ (diazomethylketone), or –oCOR (acyloxymethylketone). The peptide portion, stabilized, determines the specific selectivity of the various caspases. Thus, zVAD-fmk is a nonspecific inhibitor of almost all of the caspases. DEVD-fmk, on the other hand, is specifically selective for effector caspases such as caspases 3, 6, and 7. Table 2 gives an idea of the specific inhibitors for different caspases.

Figure 5 Structural organization and activation of caspases. The caspases are produced as pro-enzymes (32–53 kDa), including a prodomain (3–24 kDa), the large subunit (17–21 kDa) containing the active site, and the small subunit (10–13 kDa). To become enzymatically active, these three components must be proteolytically cleaved (D-x site), a phenomenon that is regulated by the prodomain itself; this allows the assembly of the large and small subunits, with the dimerization into a functional enzyme.

Figure 6 Caspase proteolytic specificity. The caspases recognize a tetrapeptide motif corresponding to the four residues P4–P3–P2–P1. While the position at P3 and P1 seems to be obligatory, the position P4 allows the classification of three subfamilies (see also Figure 1). This property has facilitated the identification of group-specific inhibitors.

In 1991, Lois Miller first identified a natural inhibitor of apoptosis, even before the discovery of caspases. The protein p35 produced by baculovirus (*Autographa californica*) is a potent and selective inhibitor of caspases. Subsequently, numerous other viral caspase inhibitors were identified, such as cytokine response modifier A (CrmA). Inhibition of caspases by these specific proteins is one of the important pathways among which viruses regulate apoptosis.

Numerous cellular proteins exist with similar actions to these viral caspase inhibitors. They are called inhibitors of apoptosis (IAPs). Table 3 shows the different viral and human IAPs with their relative inhibitory effects on each caspase.

All of the proteins which inhibit caspases, whether viral or cellular, are characterized by structural domains called Baculovirus IAP repeat (BIR); consequently, all IAP proteins are also called BIR proteins (BIRp). On the other hand, the contrary does not hold: there are BIR proteins which do not show IAP

Figure 7 Sequential activation of caspases. In general, caspases with a long prodomain are involved in the upstream regulation and activation of the apoptotic pathway; they require a tight regulation and activation, and furthermore, they cleave very specific substrates. Caspases with a short prodomain are involved in the amplification of the effector cascade, thus they have a very simple, fast, and direct activation, and they also have many substrates, which inactivation finally kills the cell. Caspase 6 seems to be able to reactivate the upstream regulatory caspases, creating a feedback forward potentiation loop that strongly enhances the amplification of the death signal. Color code is in keeping with Figure 4. The scheme has been modified from Slee EA, Adrian C, and Martin SJ (1999) Serial killers: Ordering caspase activation events in apoptosis. *Cell Death and Differentiation* 6: 1067–1074.

activity. This fact is due to the prokaryotic origin of BIR proteins which are multifunctional. Many BIR proteins in humans (e.g., survivin) are passenger proteins in the mitotic spindle and are implicated in cell division.

Caspase Knockouts

The creation of transgenic mice lacking specific caspases has been accomplished for most caspases. Table 4 displays the phenotypes for these mice. Because caspases play a determining role in apoptosis, sometimes specifically, and sometimes redundantly, the phenotypes are extremely diverse, as indicated by the table.

The role of caspases in the receptor mechanism is indicated by the caspase-8 knockout.

The similarity of the phenotypes of the knockouts of caspases 3, 9, and Apaf-1 indicates the presence of a very important mechanism in the apoptosome by which the amplification of the caspase cascade is initiated and regulated.

Caspase 8 Plays a Crucial Role in the Regulation of Death Receptors

Caspase is the initiator caspase during the activation of death receptors like TNF and CD95. Here, it is a crucial component of the death initiation signaling complex, shown in some details in Figure 8(a). In addition to activate apoptosis, recent work has provided concluding evidence that caspase 8 inhibits

Figure 8 Caspase 8 plays a crucial role in the regulation of death receptors. Downstream of death receptors like TNF, caspase 8 is part of the death inducing signaling complex, recruited by its interaction with FADD (a). Here, it inhibits the activation of RIPK3 by RIPK1, thus regulating necrosis. At the same time, caspase 8 is bound and regulated in its pro-apoptotic function by its interaction with Flip. Consequently, both apoptosis and necrosis can result from activation of the death receptor, in a regulated manner. (a) In a normal receptor, the regulated interaction of these elements allows a controlled cell death. Wild-type mice, WT, therefore have a normal development with a regulated death pathway. (b) Knockout mice for caspase 8, caspase 8^{-/-}, or for FADD, FADD^{-/-}, or double knockouts for both show an embryonic lethal phenotype due to uncontrolled necrosis by active (phosphorylated) RIPK3. (c) Triple knockouts for FADD^{-/-}, FLIP^{-/-}, and RIPK3^{-/-} have a normal cell death and develop to a normal birth, due to the absence of necrosis (driven by RIPK3) and apoptosis (driven by FADD inability to recruit caspase 8). (d) Double knockout mice for RIPK3^{-/-}; FLIP^{-/-} die during embryonic development for uncontrolled apoptosis driven by active (starts) caspase 8. Modified from Dillon CP, Oberst A, Weinlich R, et al. (2012) Survival function of the FADD–CASPASE-8–FLIP complex. *Cell Reports* 1(5): 401–407.

necrosis by inhibiting the activation by phosphorylation of the kinase RIPK3 by the kinase RIPK1. The biological evidence for this pathway has been provided very recently by work based on multiple knockout mice. Indeed, caspase 8 knockout mice (caspase 8^{-/-}), FADD knockout mice (FADD^{-/-}), and FLIP knockout mice (FLIP^{-/-}) are embryonic lethal due to uncontrolled necrosis. Complementation with RIPK3^{-/-} reverts the lethal phenotype allowing normal development. **Figure 8** shows the effect of different double and triple knockout mice lacking different components of this crucial complex.

Pathological Implications

The execution of apoptosis is dependent on the activation of caspases, and, as a result, caspases play a determining role in all pathologies of excessive apoptosis. For example, caspases play a crucial role in the *in vivo* activation of death described in myocardial infarction and in cerebral ischemia, conditions in which cell death occurs both by apoptosis and by necrosis.

Caspases can also play an aberrant role in regulatory processes determining the major propensity or vulnerability of cells to lethal insults. Examples are the possible roles played by caspases in triplet diseases such as Huntington's disease and in neurodegeneration like in Alzheimer's disease.

In the Huntington disease, low level of intracellular activation of caspase 3 liberates an amino terminal fragment of the

protein Huntingtin (four DxxD sites in a cluster), containing the Glu expansion, facilitating a pathological aggregation. In turn, this aggregate sensitizes more caspase 3, forming a vicious cycle of activation and aggregation of poly-Glu. The cell, thus sensitized, facilitates the activation of caspase 8 (from the CD95 receptor, or directly by an effector caspase, or even stimulated indirectly by the poly-Glu aggregate), determining the death of the cell. This sensitization can also occur extremely slowly (years).

In Alzheimer's disease, caspase 3 alters the normal processing of the amyloid beta precursor protein (APP), removing the carboxy terminal. APP, deprived of the intramolecular reinternalization signal, proceeds down a route of degradation that results in the formation of the amyloid beta (Aβ) peptide, which can, in turn, favor the activation of apoptosis by means not yet clearly understood.

In either case, caspase 3 seems to augment the baseline levels (threshold?) of activation of cell death, rendering the cell more sensitive to death, and participating therefore in the pathogenetic mechanisms of these important illnesses.

Therapeutic Outlook

Selective peptide inhibitors of different caspases (see **Table 2**) have been successfully developed, even though they show

Pan-caspases	IDN-6556	Caspase inhibitor	Idun	Antiapoptotic, anti-inflammatory antifibrotic	Phase-2 for HCV-HBV infection and reperfusion
	IDN-6734	Caspase inhibitor	Idun	Reduces heart attack	Phase 1, myocard infarct
	VX-799	Caspase inhibitor	Vertex / Serono	Sepsis and neuronal death	Phase1, sepsis
	MX1013	Caspase inhibitor	Maxim	Myocardial infarct, stroke, and acute liver failure	Preclinical, myocardial infarct, stroke

serious problems penetrating the cell membrane, as well as having electrophilic promiscuity and stability in solution which make them able to be attacked by biological nucleophiles such as cathepsin. While this makes them not easily adapted to clinical use, they have allowed scientists to obtain many interesting *in vitro* results. More recently, Merck (like SmithKline Beecham, BASF, Idun/Novartis, and Vertex) has in advanced stages of development new classes of low-molecular-weight nonpeptide inhibitors. These show a much higher potency and specificity, opening new therapeutic perspectives. Nonpeptide inhibitors such as isatins attain potencies 100–1000 times greater than the class of zVAD-fmk, with substantial improvements *in vivo*. These studies are still in early stages (see [Figure 9](#)), and we hope that the near future will tell as the best clinical application for this new class of drugs.

Catalysis by RNA, Structural Themes: Group I Introns

B L Golden, Purdue University, West Lafayette, IN, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Exons Segments within a gene that encode a functional cellular protein or RNA.

Introns Noncoding DNA sequences that interrupt functional genes and are removed by

splicing once the gene has been transcribed into RNA.

RNA splicing Process by which intervening sequences are removed from a transcribed RNA and the flanking exons are joined to make a functional cellular RNA.

The Self-Splicing Reaction

The self-splicing reaction of group I introns is accomplished by two sequential phosphotransesterification reactions (**Figure 1(a)**). In the first step of splicing, a guanosine nucleoside substrate (guanosine, guanosine monophosphate, guanosine diphosphate, or guanosine triphosphate) is bound by the intron and positioned for nucleophilic attack at the 5' splice site. The 3'-OH of the guanosine attacks at the phosphorus of the 5' splice site and displaces the 3'-OH of the 5' exon. This reaction results in release of the 5' exon and covalent attachment of the guanosine molecule to the intron. In the second step of splicing (**Figure 1(a)**), a conserved guanosine at the 3' end of the intron (called ω G) is positioned by the intron in a manner similar to binding of the exogenous guanosine substrate in the first step of splicing. In a reaction chemically analogous to the reverse of the first step of splicing, the 3'-OH of the 5' exon displaces the 3'-OH of ω G from the phosphate at the 3' splice site. Ligation of the 5'- and 3'-exons and release of the intron results.

Secondary Structure

Structured ribonucleic acids (RNAs), such as transfer RNAs, ribosomal RNAs, and ribozymes, do not have an extended linear structures; they are folded. Although not completely double-stranded-like genomic DNA, they have short base-paired regions formed from self-complementary sequences within the primary structure of the RNA. Group I introns have a conserved secondary structure consisting of a series of double-stranded regions labeled P1–P9 (**Figure 2(a)**). These helical regions are linked by 'single stranded', or joining, stretches of RNA labeled for the two helices that they connect (e.g., J8/7) and are capped by loops designated with an 'L'. Although most joining and loop regions are not involved in forming Watson–Crick base pairs, they usually form well-defined structures, including base pairs. These helices, loops and joining nucleotides are organized into three domains designated P1–P2, P3–P9, and P4–P6 (**Figure 2(a)**).

The P1–P2 domain, or substrate domain, spans the 5' end of the molecule and contains the 5' splice site, which is located within the short helix P1. The final nucleotide in the 5' exon is a uridine, which is base paired to guanosine on the

complementary RNA strand of the intron, forming a G•U wobble base pair. The P3–P9 domain immediately follows the P1–P2 domain in the primary structure of the intron. This domain contains the helix P7 that binds to an exogenous guanosine substrate in the first step of splicing, and to ω G in the second step of splicing. The P3–P9 domain also contains a single-stranded stretch of 5–6 nucleotides called J8/7 that is involved in binding and positioning the P1 helix, and thereby the 5' splice site. The P3–P9 domain is interrupted by the P4–P6 domain. The P4–P6 domain, folds together with the P3–P9 domain, to comprise most, if not all, of the catalytic core of the intron. This domain also participates in splice-site recognition by binding the guanosine within the G•U wobble base pair at the 5' splice site.

Tertiary Structure

The secondary structures in the intron fold in a magnesium-dependent manner to form a compact tertiary structure much like a globular protein enzyme (**Figure 2(b)**). Formation of the folded structure is absolutely dependent on divalent metal ions, usually Mg (II), which serve to stabilize the structure by neutralizing the negative charges of the phosphate groups on the RNA backbone and by organizing the RNA into specific structures required for proper folding. In crystal structures of group I introns and their domains, magnesium ions are seen bound within the major groove, mediating the close approach of RNA helices, and stabilizing unusual conformations that allow the formation of intramolecular RNA–RNA contacts. Folding of the RNA creates binding sites for the P1 helix and the guanosine nucleotide cofactor described below.

The tertiary structure of group I introns has been extensively investigated by X-ray crystallography. These studies have provided high-resolution structural information for one of the domains and medium-resolution for three different group I introns. Complementary work has been performed using solution biochemistry to probe the rate of the chemical reactions of vast array of group I introns containing single atom modifications. These data can be put together to help elucidate the structural basis for group I intron catalysis.

The crystal structures of the group I introns reveal many of the strategies used by RNAs to form tertiary structures. Perfectly double-stranded helical RNAs do not tend to form stable tertiary structures. The structural information encoded

Figure 1 Reactions of a group I intron RNAs. (a) The self-splicing reaction is initiated by binding of a guanosine nucleoside. The 3'-OH of the nucleoside is activated for attack at the 5' exon–intron junction. In the first step of splicing, the guanosine becomes covalently attached to the intron, and the 5' exon (pink) is cleaved from the intron (blue). In the second step of splicing, the 3'-OH of the 5' exon attacks at the junction of the intron and the 3' exon (green). This reaction links the 5' and 3' exons and releases the intron. (b) The intron can be converted into a ribozyme capable of cleaving an RNA substrate using a guanosine nucleoside. The substrate RNA, like the 5' exon in the self-splicing molecule, can base pair to the 5' end of the ribozyme that is called the internal guide sequence (IGS).

Figure 2 Secondary and tertiary structure of a group I intron. (a) The sequence of a group I intron folds into a secondary structure containing a series of base-paired regions called P1–P9. These short duplexes are linked by 'single-stranded' nucleotides designated 'J' and capped with loop sequences designated 'L'. These secondary structural elements are organized into three domains termed P1–P2, P3–P9, and P4–P6 that are shaded yellow, green, and pink, respectively. The P1 helix is formed by base pairing between the 5' end of the ribozyme and the 5' intron. Folding of the ribozyme brings the 5' splice site (*) and the guanosine substrate-binding site (*) into proximity. (b) The three-dimensional structure of a group I intron from *Azoarcus*. The P1–P2 domain (yellow) is bound and positioned by cooperative action of the P4–P6 (red) and P3–P9 (green) domains.

by the RNA sequence is sequestered within the Watson–Crick base pairs of a perfect helix, and the exposed, accessible surface is limited to the backbone and the shallow minor groove.

To facilitate tertiary structure formation, 'flaws' in the helices are often present, containing base pairs other than the standard Watson–Crick A–U and G–C base pairs. These can readily form in between helices and, when present, they

distort the major and minor grooves of the double-stranded helix to create distinct shapes and to expose hydrogen-bonding groups on the bases. This forms complementary surfaces that allow RNA domains to pack together. Loops, particularly four nucleotide sequences called tetraloops, which cap helices can also form distinct structures that mediate long-range tertiary interactions. These interactions are further stabilized by hydrogen bonds that can form between the 2'-OH groups of the ribose backbone. These tertiary structures are termed 'ribose zippers'.

Substrate Recognition

Group I introns have binding sites for two substrates: a guanosine nucleophile and a short duplex containing a G•U wobble base pair.

The Guanosine-Binding Site

The guanosine substrate (in the ribozyme reaction and in the first step of splicing) and ω G (in the second step of splicing) are recognized by a single guanosine-binding site located in the major groove of helix P7, a distorted double helix with a narrowed major groove. A G–C base pair near the 'top' of the P7 helix provides significant specificity for the guanosine base (Figures 3(a) and 3(b)). Recognition of the guanosine base can largely be described as a base triple. The recent crystal structures reveal that this base triple is stacked between two additional base triples, forming a snug-binding pocket for the guanosine substrate. The orientation of the ribose group of the guanosine comes from magnesium ions bound within the intron's active site (Figure 3(b)).

Helix P1 and 5' Splice-Site Recognition

The 5' splice site is recognized in the context of a short double-stranded region called P1. In self-splicing introns, helix P1 is formed by intramolecular base pairing between the 5' exon and a complementary sequence near the 5' end of the intron, creating a stem-loop structure (Figure 2(a)). The helix is 3–6 base pairs in length, depending on the specific intron, and the final base pair is a G•U wobble pair composed of the last nucleotide in the 5' exon, and a guanosine near the 5' end of the intron. G•U wobble pairs, like A–U base pairs, contain two hydrogen bonds between the two bases (Figures 3(a) and 3(b)), but the geometry of the pair is slightly altered compared to a Watson–Crick base pair: the guanosine base is pushed slightly into the minor groove and the uridine base is pushed slightly into the major groove. This base pair can be readily accommodated within an RNA double helix and is about as stable as an A–U base pair.

The intron may be converted into a ribozyme by splitting the P1 helix into two molecules (Figure 1(b)). The first strand is formed from the very 5' end of the ribozyme and is called an internal guide sequence (IGS; Figure 1(b)). The second strand serves as a substrate for the ribozyme. It is complementary to the first strand, maintains the G•U wobble base pair, and extends for at least one nucleotide beyond the cleavage or splice site.

P1, whether composed of a hairpin in the self-splicing intron or composed of an intermolecular duplex in a ribozyme form, docks into the active site of the ribozyme. Docking is stabilized by interactions between the single-stranded regions J2/3 and J8/7 and the minor groove of P1. These contacts are primarily hydrogen bonds to the ribose backbone and, therefore, are sequence independent. Except for the G•U wobble

Figure 3 Substrate interactions with the group I intron core. (a) Interactions between the three domains in the transition state. Near the transition state for the ribozyme reaction, the bond between the 5' exon and the intron is partially broken and the bond between the guanosine substrate and the intron is partially formed. At least two magnesium ions help orient the substrates and stabilize the transition state, facilitating catalysis. The G•U wobble at the 5' splice site is shaded yellow. The guanosine bound in the guanosine-binding site is shaded green. Adenosines within the P4–P6 domain involved in positioning the G•U wobble are shaded pink. Magnesium ions that participate in catalysis are drawn as spheres. Hydrogen bonds and metal interactions are indicated by dashed lines and partial bonds are indicated by dotted lines. (b) The crystal structures of group I introns reveal the interactions that orient the G•U wobble that defines the 5'-cleavage site and the guanosine-nucleotide substrate.

Figure 4 Interactions between the three domains in the transition state. Near the transition state for the ribozyme reaction, the bond between the 5' exon and the intron is partially broken and the bond between the guanosine substrate and the intron is partially formed. Three magnesium ions help orient the substrates and stabilize the transition state, facilitating catalysis. The G•U wobble at the 5' splice site is shaded yellow. The guanosine bound in the guanosine-binding site is shaded green. Adenosines within the P4–P6 domain involved in positioning the G•U wobble are shaded pink. Magnesium ions that participate in catalysis are drawn as spheres. Hydrogen bonds and metal interactions are indicated by dashed lines, and partial bonds are indicated by dotted lines.

base pair, identity of base pairs within the P1 helix is not critical for recognition. Thus, by appropriate variation of the nucleotides in the IGS, almost any RNA substrate containing a uridine can be recognized and cleaved by a group I ribozyme.
